SUBJECT INDEX 1185

Preface

For more than a decade some chemists interested in petroleum technology have maintained that the numerous hydrocarbons abundantly available in the product of our oil wells will ultimately provide the basis of a new organic chemical industry yielding new substances in as great variety and of as essential utility to civilization as the products of coal tar. The realization of this dream has been hindered by the extraordinary difficulties of separating chemical individuals in a satisfactory state of purity from the complex mixture which constitutes the mother substance, but in spite of the uncertainties of working with partially purified raw materials a vast amount of information has been accumulated on the behavior of individual hydrocarbons derived from petroleum.

Interest in the chemical utilization of aliphatic hydrocarbons has been greatly stimulated within the last few years by the development of more efficient methods of fractional distillation for separating the lower-boiling constituents of petroleum and of fractional solution in a variety of solvents for isolating higher-boiling compounds. Progress toward the quantity preparation of pure compounds has been rapid and the literature bearing upon their elaboration has become voluminous. During the past few years the amount of material on the subject has increased several fold and the number of investigators studying problems related to it has grown enormously.

In this situation the difficulties faced by the individual research worker in collecting and collating the widely diffused literature bearing upon his problem have become well-nigh insurmountable. Such a task has been in progress in the author's laboratory for some years and so great was the mass of material accumulated and the labor involved in making it usable that the decision was reached to publish the result in order to place it at the disposal of the many others interested. That is the reason for the present volume. Every effort has been made to make it complete and to include in it references to all published material of both purely scientific and industrial interest as well as to the vast amount of information contained in patents on the subject.

In the preparation of the manuscript many collaborators have co-operated and the author takes this opportunity to extend his thanks to them. Prof. Julius von Braun, Prof. J. R. Bailey, Prof. H. B. Haas, Dr. D. A. Howes, Dr. Ernest B. Kester, Prof. Donald B. Keyes, Mr. W. B. Plummer, and Dr. Sherlock Swann, Jr., have materially assisted in the preparation of certain chapters. The members of the research and technical departments of the Standard Oil Company of New Jersey have given valuable constructive criticism of many parts of the volume. I wish especially to express my appreciation to Dr. H. M. Stanley and to Mr. D. H. Killeffer; to Dr. Thomas C. Whitner, Jr., Mr. Ferdinand F. E. Kopecky, and other members of my laboratory staff; and to Dr. Frank B. Root and the Ellis-Foster Company for their contributions to this huge task.

Montclair, N. J.
1934

Introduction

World production of petroleum is approaching a quarter of a billion tons annually but, with new deposits constantly being found—indicative of the widespread distribution of oil throughout the land and under the sea—the apprehensions of a decade ago that the supply of this essential raw material would soon be exhausted no longer obtain. The replacement of such fears by the assurance of tremendous supplies for a long period to come of this important commodity should have given an impetus to pure chemical research in the domain of petroleum commensurate with the vastness of the deposits.

This, however, appears not to have been the case. Despite the great number of chemists, physicists, engineers and other technically trained men engaged in the study and handling of petroleum, very little is known thus far of its actual chemical make-up.

In certain other important chemical industries originating by virtue of a supply of particular substances, comprehensive research of a scientific character preceded the commercial development of the field. Of these, the coal-tar industry stands foremost. So provocative of industrial recognition have been the results of scientific study of coal-tar hydrocarbons that the layman frequently asks why the petroleum chemist does not direct his skill similarly to the chemical utilization of the hydrocarbons of crude oil.

There exists, however, a significant difference between the two groups of hydrocarbons from coal tar and from crude petroleum in that the former (at least so far as the lower and intermediate members are concerned) are easily separated one from another, which permits the properties of the chemically individual hydrocarbons to be ascertained with comparative ease. As a result of such studies of the pure substances, commercial products have become available for treatment and conversion by well-understood industrial methods. The group of terpene hydrocarbons has been similarly well elucidated in the hands of chemists.

Why, then, is so little known chemically about a commodity of such import as petroleum? The following explanation is offered.

Unlike the reactive terpene hydrocarbons and most of those present in coal tar, the hydrocarbons of petroleum oil are, in the main, comparatively indifferent to the majority of the usual conversion reagents. This observation coupled with the recognition of the possible existence of an extraordinary number of hydrocarbon individuals in crude oil and its distillates has impelled many chemists to view with dismay the prospect of founding an extensive chemical industry on petroleum. Hence for the most part they rest content to continue their efforts mainly in the direction of the treatment of crude oil by refining procedures which, although often displaying chemical talent and ingenuity of high order, perforce are conducted largely on an empirical plane. Still others look for some explorer to rise from the ranks with banners flying and lead them from this empiricism along a course as definite, informative and expansive as that so well charted in the chemistry of coal-tar oils.

No such leader has yet appeared. Here and there a man of science resolves some small part of the disorder. Witness, for example, the work of Julius von Braun on naphthenic acids and the researches of J. R. Bailey on the nitrogen compounds of petroleum.

A group of pessimists, by no means small in number, is not lacking to hold out a warning hand of futility to these progressives and to call attention to those calculations which show that a paraffinic hydrocarbon of, say, nine carbon atoms could be represented by 35 isomers (55, if stereoisomers are included) and that one of 20 carbon atoms would have 366,319 possible isomers, a number swollen by including stereoisomers to the enormous figure of 3,395,964!

That petroleum contains a multiplicity of isomers is a common observation. That all isomers theoretically possible are to be found therein is by no means probable. In fact experimental work has already demonstrated that of a family of isomers found in a petroleum distillate some one member usually predominates.

A further obstacle to rational chemical development has been the pronounced variation between crude petroleums from different parts of the world. Those from the Pennsylvania oil regions, for example, are commonly considered highly paraffinic, those from California include large percentages of aromatic compounds, and those from Russia and Galicia contain substantial proportions of hydroaromatics. Methods, therefore, which will allow the identification of certain types of hydrocarbons in one crude petroleum may not be applicable to another in which entirely different hydrocarbons predominate. This variation in composition adds to the confusion with respect to the presence of individual hydrocarbons.

Despite the foregoing, observers note a slow but steady advance in the chemistry of petroleum both technologically and scientifically. Technology has, perhaps, shown greater progress than strictly scientific knowledge. Thus, the urgent need for toluene during the World War resulted in the development of cracking processes which yielded that hydrocarbon in significant quantities just as other commercial needs have produced other developments.

At about the same time the experimental work conducted by the author supplied the oil industry with methods for the conversion of olefins from cracked products into secondary alcohols. From these by catalytic oxidation or dehydrogenation various ketones became available. Numerous esters prepared from the alcohols found favor in the lacquer industry and elsewhere.

This enterprise established in one of the refineries of the Standard Oil Company of New Jersey probably represents the first permanent industrial plant for making chemical derivatives, other than hydrocarbons, from petroleum.

Later work by others has resulted in the commercial production of glycols and their ether derivatives, well received by the coating industry.

The pages following embrace as comprehensive a review of the chemical derivatives of petroleum as publication limitations permit. That there have been many disappointments in the laboratories of petroleum chemists when the hope of synthesis of industrially important compounds from petroleum has failed is to be expected. The surprising fact is that results of such far-reaching importance in petroleum chemistry already have been attained.

In a comprehensive work of this kind, including as it does mention of the conclusions of a vast number of investigators, an appraisal of the merits and demerits of all the proposals offered manifestly is impossible. The author, therefore, has had to content himself for the most part merely with a brief statement of the findings of and the conclusions drawn by the investigators enumerated

CHEMISTRY OF PETROLEUM DERIVATIVES

Chapter 1

Chemical Nature of Petroleum and Natural Gas. Pure Hydrocarbons from Petroleum

Crude petroleum as it issues from wells consists mainly of a mixture of hydrocarbons of many chemical types and of varying degrees of molecular complexity. Besides hydrocarbons, smaller proportions of compounds of oxygen, nitrogen, and sulphur are often present together with mechanically held gas, water, clay, and inorganic substances in solution or colloidal suspension. Petroleums from different localities, and even from dissimilar oil sands in the same field, often exhibit great variations in appearance, chemical composition and properties.[1] For example, the crude oil of the Kettleman Hills field, California, frequently consists almost entirely of comparatively volatile hydrocarbons and has been marketed as a motor fuel directly without distillation or refining.[2] On the other extreme, the black asphaltic and highly sulphurous Mexican crudes often contain no gasoline fractions whatever. Petroleums differ not only in their content of impurities (such as sulphur compounds) but also in the chemical type and average molecular complexity of the hydrocarbons present, which may range from the simplest gaseous members of the paraffin series to hydrocarbons of molecular weight exceeding 1000.[3] Besides the paraffin and cycloparaffin (naphthene) hydrocarbons, benzenoid hydrocarbons as well as more complex polynuclear aromatic and cycloparaffin hydrocarbons also occur in crude petroleum.

The existence of unsaturated hydrocarbons in crude petroleum, prior to distillation, is a question which has aroused considerable controversy. Certain unsaturated hydrocarbons and terpene-like substances have been reported by Zaloziecki[4] and LeBel,[5] and Markownikow and Oglobin[6] obtained evidence of the presence of hydrocarbons of the acetylene series. Most of the work on this subject has been carried out on distillates, i.e., fractions obtained on subjecting the crude oil to distillation, so that these unsaturated products may have been formed by pyrolysis.[7] When distillation is carried out at low temperatures and pressures, the proportion of unsaturated substances in the gasoline and kerosene fractions is usually exceedingly small.[8] Most of the published analytical figures for gasoline and kerosene fractions of various crudes show the presence of relatively small amounts of unsaturated hydrocarbons.[9] Though the complete absence of unsaturated hydrocarbons (of the gasoline and kerosene range) from *crude* petroleums cannot be presumed on the evidence available, it appears that the proportions of such hydrocarbons, if they are present at all, are usually quite small.

[9] A bibliography of chemical analyses of petroleums is given in Redwood, "A Treatise on Petroleum," Charles Griffin and Co., Ltd., London, 1913, 1, 237-267.

NATURAL GAS

The simpler hydrocarbons of the paraffin series are normally gaseous and occur in enormous quantities in the so-called natural gas which frequently accompanies crude petroleum. Natural gases, which may be regarded as gaseous petroleums, also exhibit great variations in chemical composition, but for the most part, they consist of lower paraffins: methane, ethane, propane, with smaller quantities of butane, pentane, and other hydrocarbons up to octane, together with smaller proportions of nitrogen, carbon dioxide, hydrogen sulphide, and, in a few cases, the rare gas helium.[10] Small proportions of the vapors of benzenoid and cycloparaffin hydrocarbons (naphthenes) are also undoubtedly present in some gases which are in contact with aromatic or highly naphthenic crudes. Thus, Erskine[11] found that a sample of Pennsylvania natural-gas gasoline, recovered by absorption, contained 0.6 per cent of benzene, 0.6 per cent of toluene and 1.2 per cent of m-xylene. The presence of cyclopropane and cyclobutane in natural gases has been suspected though not definitely proved.[12] On the other hand, gases such as olefin or acetylene hydrocarbons, carbon monoxide and hydrogen, which are characteristic products of pyrolytic reactions, have never been found in natural gas.

Natural gases are roughly divided into two classes, "dry" and "wet" gases. High-pressure gas from new fields or gas not associated with crude petroleum, and containing only relatively small amounts of the higher gaseous paraffins, is called dry gas, whereas low-pressure gas associated with petroleum, and containing relatively large amounts of easily liquefiable hydrocarbons, is termed wet gas. Although the majority of gas wells do not yield oil, gas invariably accompanies oil in the strata. Dry gases consist mainly of methane with varying amounts of nitrogen and carbon dioxide. In illustration of the great variation in composition of gases from different localities, it may be noted that Botolfsen[13] described one containing very large proportions of nitrogen and a Mexican natural gas, consisting of almost pure carbon dioxide, has been exploited as a source of "dry ice" (solid carbon dioxide).[14]

Natural gas occurs in parts of the world where petroleum is found—in Russia, Rumania, Poland, Burma, Persia, Mexico, South America, Canada, and more especially in the United States. It also probably occurs in the atmospheres of the large planets, lines due to methane molecules having been identified in the spectra.[15] Practically 98 per cent of the world's commercial production of natural gas is accounted for by the United States. Although over half the states of the

United States produce some natural gas, the principal fields are located in Oklahoma, Texas, California, Louisiana, West Virginia, and Pennsylvania. The production of this gas in the United States in 1928 was in the neighborhood of 1,568,139,000,000 cubic feet.[16]

In chemical composition, natural gases from different localities exhibit wide variations, as may be seen from the following tables. It is desirable at this stage to point out that many of the older, and even some of the more recent, analyses are untrustworthy on account of the inadequacy of the analytical methods employed. In the older methods of analysis, for example, no differentiation was made between the various homologous paraffins, the total hydrocarbon content being usually recorded simply as methane. The development of low-temperature fractionation methods of analysis has rendered possible a fairly accurate differentiation and estimation of the individual hydrocarbons present.[17]

Table 1 contains analytical figures for various natural gases in the United States.[18] Though no differentiation is made betweeen the individual gaseous hydrocarbons, these values clearly reveal the wide variation in the quantity and type of the non-hydrocarbon content of the gases.

Podbielniak.[22] In all of these, low-temperature fractionation methods were employed to separate and estimate the individual hydrocarbons. The development of analytical methods involving careful low-temperature fractionation through a special column has been greatly advanced by the work of Podbielniak.[23] Typical analyses of various gases in the Podbielniak apparatus are given in Table 2.

TABLE 2.—*Natural Gas Analyses.*
(Per cent by volume)

Gas	Methane	Ethane	Propane	n-Butane	Isobutane	Pentanes and Higher Hydrocarbons
Wet gas	65.7	12.4	11.3	5.0	1.8	3.9
Dry gas	77.6	6.9	10.1	4.8		0.6
Wet gas	53.3	7.3	17.7	10.9	3.3	7.5
Residual gas	87.6	6.9	4.7	0.3	0.2	0.3
Natural gasoline (liquid)	—	3.8	6.7	19.7	5.2	64.6

It is not necessary to include a large number of complete analyses of various American gases in this discussion, since the composition of such gases depends very largely on immediate operating conditions and may vary somewhat from day to day. As might be expected, the dry gases show a greater constancy of composition over extended periods than wet gases.

The natural gases of Canada, particularly those of the provinces of Ontario and Alberta, have been considered from the point of view of their possible industrial utilization.[24] Rosewarne[25] gave the following typical analyses by low-temperature fractionation of gases from wells in the Turner Valley field of Alberta during 1930. (See Table 3.)

TABLE 3.—*Natural Gases from Turner Valley, Alberta.*

Low-temperature fractionations of various Russian natural gases have also been made by Nametkin and others,[27] and the composition of gases from the Makat and Baku oilfields has been reported by Trebin and Luchinskii [28] and by Rabinovich,[29] respectively. The gases from the neighborhood of Baku (Apsheron peninsula) frequently possess a high content of carbon dioxide. Some Italian natural gases have been examined by Levi, Padovani, and Busi [30] and those of Poland by Kling, Beckówna and Kirschbaum.[31]

Utilization of Natural Gas. Natural gas is used on a very large scale for the manufacture of carbon black.[32] Advances in our knowledge of the chemical transformations of the simpler paraffin hydrocarbons lead to the belief that natural gas is a chemical raw material of the highest promise, though so far only the fringe of this vast subject has been explored.[33]

The main use for natural gas is as a domestic and industrial fuel.[34] The wet gases, however, are now invariably treated for the recovery of liquid constituents, which include the paraffin hydrocarbons from butane [35] up to and including octane. The liquid obtained by stripping wet natural gas is called natural-gas gasoline and is an important source of volatile constituents for blending with gasoline obtained by distillation of crude petroleum or by cracking. When mixed with heavier naphtha, it yields a mixture comparable with the straight-run product.

The extraction of gasoline from natural gas is effected on a large scale by three distinct methods: (1) compression, (2) absorption in oil, and (3) adsorption on solids, such as activated charcoal.[36] The properties of gasolines prepared by these processes differ to some extent, the compression process yielding a very volatile product. Before blending such natural gasoline with straight-run gasoline it is necessary, therefore, to remove some of the more volatile ("wild") constituents. This process, yielding a gasoline of definite vapor pressure, is called stabilization. The most objectionable constituent from the point of view of volatility is propane, which must be removed almost entirely to obtain a satisfactory blending material. The stabilization process, which consists essentially of fractional distillation under pressure, also removes butane.

Huge amounts of liquefied propane and butanes thus produced are now being utilized for a number of purposes, particularly as a fuel for domestic and indus-

trial consumption.[37] So-called liquefied petroleum gas, consisting of propane, n-butane and isobutane, which are gaseous under normal conditions but liquid under pressure, is now transported in steel cylinders and in special tank cars under pressure. This material is useful not only as an industrial and domestic fuel in districts remote from towns, but it can also be used for enriching manufactured gas and water gas [38] and as a substitute for acetylene in welding. From a chemical standpoint, liquefied petroleum gases, available in large quantities at a relatively low cost, appear to be ideal raw materials for the manufacture of certain organic chemicals. The available supply of these liquefied gases is very great —it has been estimated that the natural gasoline industry of the United States could easily produce 5,000,000 gallons of propane and 3,500,000 gallons of the butanes daily without appreciable diminution of natural gasoline supply.[39]

Because of its freedom from vaporization difficulties at low temperatures, propane is finding special application for domestic purposes, and the use of commercial butane as a carbureting agent in gas manufacture is one of the outstanding developments in the gas industry.[40] Liquefied petroleum gases have been proposed for the extraction and refining of rosin and gums [41] and for the purification of oils and asphalts.[42] The gases, particularly propane, can be used also in refrigerating equipment.[43] Pentane has been suggested for treatment of paper preliminary to subsequent impregnation with viscous materials for the manufacture of insulation.[44] Methane has been investigated as a fuel for motor-driven vehicles, the operating results being favorable.[45] An explosive, consisting of an oxidizing agent, a liquefied volatile hydrocarbon and an absorbent, which loses its power soon after being loaded into a bore-hole, has been proposed by Wulff.[46]

In separating a condensate from a gas by compression or adsorption, the efficiency of separation is increased if a substance having a lower boiling point than any other constituent of the condensate is added.[46a] Thus a use is found for propane in effecting a more efficient separation of benzine from casinghead gas. The propane is subsequently removed from the condensate and again utilized.

Natural gas is also a raw material for the manufacture of hydrogen.[47] For this purpose, the gas is heated to a high temperature (usually about 1000° C.) to decompose the hydrocarbons into their elements. The thermal decomposition of hydrocarbons is discussed more fully in Chapters 2 and 7.

As previously stated, the liquefied petroleum gases consist of propane, n-butane, and isobutane. Propane can be easily separated on a large scale by efficient fractionation and with modern equipment the separation of butane and isobutane can also be accomplished. Such a separation, therefore, makes these three paraffin hydrocarbons available for purely chemical utilization.

NATURAL-GAS GASOLINE

Natural-gas gasoline, or casinghead naphtha, is the liquid hydrocarbon mixture extracted from natural gas by compression,[48] absorption in oil,[49] or adsorption on solids.[50] It is distinguished from straight-run products by its higher volatility and lower boiling range. In general, it consists of the lower members of the paraffin series from propane up to octane, though propane should be absent from the stabilized product.[51] Examination of samples of natural gasoline from many localities in Texas, Oklahoma, Kansas, Kentucky, Ohio, and West Virginia has shown that they all contain substantial proportions of the pentanes, of which three chemical individuals exist:

Pentanes	Boiling Point ° C. at 760 mm.[52]
Normal pentane $CH_3(CH_2)_3CH_3$	36.2°
Isopentane $(CH_3)_2CH.CH_2.CH_3$	28.0°
Tetramethylmethane $(CH_3)_2C(CH_3)_2$	9.5°

Natural gasolines contain from 20 to 40 per cent of normal and isopentane but tetramethylmethane (neopentane) is the least abundant, having been found to the extent of only 2 per cent in many natural-gas gasolines from Texas and West Virginia. Normal butane, boiling at 0° C., is present in natural-gas gasoline in substantial amounts but no hydrocarbon occurs boiling between 0° C. and 28° C. with the exception of traces of tetramethylmethane. Of the hydrocarbons boiling above 36° C. about 10 per cent consists of hexanes boiling at 58° C. (diisopropyl) and 62° C. (dimethylpropylmethane) with only a trace of trimethylethylmethane boiling at 49° C. According to Ayres,[53] natural-gas gasoline contains no unsaturated hydrocarbons and no cyclic hydrocarbons boiling below the hexanes.

The composition of a typical American natural-gas gasoline has been investigated by Anderson and Erskine.[54] The sample was first separated into four fractions (each with boiling ranges of about 20° C.) in the neighborhood of the boiling points of the normal paraffins of from five to eight carbon atoms. Three distillations of the pentane fraction with a regulated temperature still-head resulted in the isolation of isopentane (boiling point, 27.8°-28.3° C.) and n-pentane (boiling point, 35.5°-36.0° C.). From the hexane fraction, 2-methylpentane (isohexane) and n-hexane were obtained by a series of four distillations. Similarly, 2-methylhexane (isoheptane) and n-heptane were separated from the heptane fraction. Table 5 gives the approximate composition of the natural-gas gasoline.

2-Methylpentane	9
n-Hexane	15
2-Methylhexane	8
n-Heptane	12
Octanes	4
Absorption oil	2

In addition to paraffin hydrocarbons, which form the preponderating constituents of casinghead gasoline, small proportions of aromatic hydrocarbons (as well as the simple naphthenes) are frequently present. Erskine[55] found benzene, toluene, and m-xylene even in a highly paraffinic Pennsylvania natural-gas gasoline. Gases which have been in contact with highly aromatic crudes such as those of Borneo (Koetei) and Rumania (Dacic) are likely to contain large amounts of benzene and its immediate homologues. Similarly, the simple naphthenes (cyclopentane and cyclohexane and their immediate homologues) are probably present in gases derived from highly naphthenic crudes such as those of Southern Russia.[56]

A condensate obtained from pipe lines of the Terrebonne gas fields near Houma, La., having a much higher boiling range and specific gravity than ordinary casinghead naphtha, has been investigated by Coates and Tims.[57] A study of the fraction of this condensate boiling at 215°-217° C. and having the formula $C_{12}H_{22}$ showed it to be identical with a similar fraction from a crude oil of Jennings, La., studied by Coates[58] in 1906. It was believed that alkyl derivatives of dicyclopentyl were present.

CRUDE PETROLEUM

Disregarding the non-hydrocarbon constituents, which on the average represent only a very small percentage of the total, crude petroleum is essentially a complex mixture of hydrocarbons of all classes and degrees of complexity. Since, from a theoretical standpoint, there is an enormous number of possible individual hydrocarbons possessing molecular weights up to 1000,[59] it is not surprising that the physical and chemical properties of crude petroleums from different sources vary considerably.

[55] *Ind. Eng. Chem.*, 1926, 18, 722.

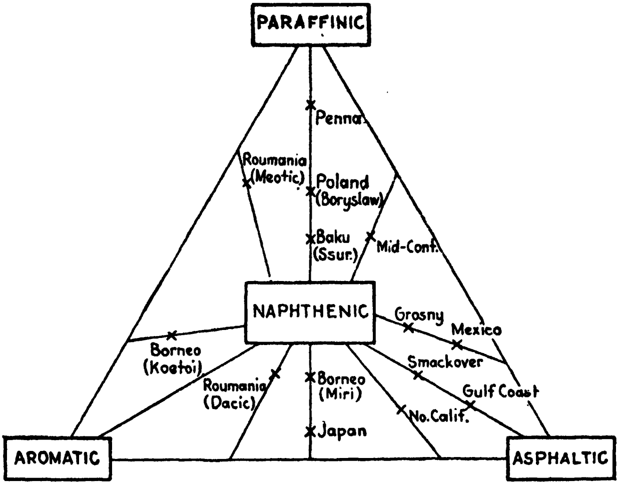
[56] Analysis of a Grozny natural gasoline is reported by Isaev, Egorov and Grigoriev, *Grozn. Neft.*, 1932, 2 (3-4), 49-53; *Brit. Chem. Abs.* B, 1933, 134.

[57] *Ind. Eng. Chem.*, 1922, 14, 219.

[58] *J.A.C.S.*, 1906, 28, 384.

[59] Henze and Blair (*J.A.C.S.*, 1931, 52, 3077) have shown that there are 62,491,178,805,831 isomeric paraffins containing 40 carbon atoms.

Crude petroleums have been roughly classified in the past as paraffin base, naphthene base, or asphalt base. The first two classes contain a preponderance of paraffin and naphthene hydrocarbons, respectively, in their lower fractions, whereas the asphalt base crudes, as their name implies, contain asphaltic substances (i.e., high molecular weight hydrocarbons with relatively low hydrogen content, as well as high molecular weight oxygenated substances) in their higher fractions. All possible variations among these classes are known, crude petroleums containing both paraffins and asphaltic substances being termed "mixed-base" oils. However, from a purely chemical standpoint this system of classification is quite inadequate since even the most paraffinic crudes contain cyclic hydrocarbons in increasing amount as the boiling point of the fractions rises.



Courtesy McGraw-Hill Book Co., Inc.

FIG. 1.—Diagram Showing Probable Composition of Various Crude Oils. (Gruse.)

In the system used by Gruse,[60] crude petroleums are classified as paraffinic, aromatic, and asphaltic, the naphthenes being present in varying proportions in all classes. To illustrate the probable composition of various crudes, Gruse employed the triangular diagram given above (Fig. 1).

The detection of individual hydrocarbons in crude petroleum is one of the most difficult problems of organic chemistry. Apart from a few special chemical methods of attack, strictly limited in their scope, the only direct methods of investigation available are fractional distillation and fractional crystallization, both of which are tedious and time-consuming and none too dependable.

Fractional distillation of the low molecular weight hydrocarbons of petroleum has made possible the definite identification of a few of the simpler members. The differences in boiling points (and consequently vapor pressures) of hydrocarbons diminish with increasing molecular weight, and at the same time the number of possible isomers increases rapidly.[61] In addition to this difficulty, the

[60] Gruse, "Petroleum and its Products," McGraw-Hill Book Co., Inc., New York, 1928, 3.
[61] See Henze and Blair, *loc. cit.*

separation of the normally liquid hydrocarbons is complicated still further by the formation of constant-boiling mixtures. Two isomers or two totally different hydrocarbons may possess the same boiling point, consequently the isolation of a fraction of constant boiling point from fractions other than the lowest-boiling ones is by no means an indication of the presence of a pure chemical individual. Much of the older work on the identification of pure chemical individuals in petroleum by fractional distillation methods is unreliable for these reasons and unwarranted conclusions were often drawn from such totally inadequate data. Of the large number of hydrocarbons which are said to have been isolated from petroleum, only a few have been indubitably proved to be present. Though many of the others may, and very likely do, actually occur in various crudes, the evidence adduced for their supposed presence is, in most cases, utterly worthless. Washburn[62] described tests for purity and evidence of identity for hydrocarbons isolated from petroleum and recommended that at least five properties—refractive index, density, boiling point, freezing point, and halogenation behavior—should be reported before identification is established. Esau[63] observed that the purity of hydrocarbons could be tested by measuring the change of temperature produced on submitting them to the action of short electrical waves (of frequencies of the order of 10^8 hertz).

Except in a very few cases it is a matter of the greatest difficulty to separate any hydrocarbon of more than six or seven carbon atoms in a pure state from crude petroleum by fractional distillation. Other methods of isolating pure hydrocarbons from petroleum are available in special cases. Thus, the higher paraffins are solids which may be resolved by laborious fractional crystallization. Certain solvents appear to possess selective solvent properties towards particular types of hydrocarbons, though the separation of pure individuals by such means is difficult. Nevertheless, selective solvent action may be employed to concentrate certain types of hydrocarbons into one or more fractions. An example of this solvent selectivity is the large-scale use of liquid sulphur dioxide to extract aromatic hydrocarbons (together with some unsaturated hydrocarbons if they are present) from kerosenes. Furthermore, certain methods have been developed for roughly determining the various classes of hydrocarbons in gasoline (and to a smaller extent in kerosene) but they are not applicable to fractions boiling above this range.

STRAIGHT-RUN GASOLINES

Straight-run gasoline, the lowest fraction obtained from crude petroleum by straight distillation, is a mixture of hydrocarbons of the paraffin, benzene, and naphthene (cycloparaffin) series. Olefins have been reported from time to time but careful work has indicated that these substances are present in small quantities only, as already mentioned, and the proportions probably depend upon the conditions of distillation.

The gasolines produced from American crudes, especially from the Eastern gasolines, and to a lesser extent from the Mid-Continent ones, are paraffinic in nature. The asphaltic oils of the Gulf Coast and California apparently produce gasolines with larger proportions of naphthene hydrocarbons (and dissolve in sulphuric acid to a greater extent) than the two mentioned. Although all American gasolines probably contain some aromatic hydrocarbons (only in small quantities in most cases, especially Eastern gasolines), some from California, on the other hand, contain high percentages of aromatics.[64] Table 6 gives analyses (in terms of classes of hydrocarbons) of various straight-run gasolines of the United States.[65] In view of the controversy as to the adequacy of the methods employed, these data should be considered as only approximate.

In other parts of the world, gasolines of widely divergent chemical compositions are obtained.[66] Gasolines with large proportions of naphthene hydrocarbons are produced from the crudes of South Russia (Surakhany), Rumania (Dacic), Japan, and certain parts of Borneo. According to Kewley,[67] Miri (Borneo) benzine consists of 80 per cent of naphthenes, 15 per cent of paraffins, and only 5 per cent of aromatic hydrocarbons. On the other hand, the gasoline from Koetei

(Dutch Borneo), which contains upwards of 40 per cent of aromatic hydrocarbons (as well as 26 per cent of paraffins and 35 per cent of naphthenes), was used as a source of toluene during the World War in the manufacture of TNT.[68]

The systematic work of Young and Thomas[69] led to the definite identification of n-pentane, isopentane, n-hexane, isohexane, n-heptane, and isoheptane in American petroleum. The presence of isomeric hexanes and heptanes was considered likely but not definitely proved in their work. Several of the higher paraffins were said to have been identified by fractionation methods but it is very doubtful whether the products obtained were pure. Other work in this connection is that of Brown and Carr,[70] who fractionated a straight-run gasoline from the Cabin Creek field up to the nonane fraction, using a semi-laboratory fractionating column and starting with 135 gallons of oil. Scores of fractions were obtained which had distillation curves with a semblance of flatness but pure compounds were not isolated. In addition to indications of the presence of butane, benzene, cyclopentane, toluene, isoheptane, and certain of the nonanes and decanes, fractions were identified having the boiling points of isopentane, n-pentane, isohexane, n-hexane, n-heptane, isooctane, n-octane, and n-nonane.

A study of the hexane fraction of an Oklahoma gasoline (straight-run) was made by Bruun and Hicks-Bruun.[71] Careful fractionation concentrated the hexanes into a series of constant-boiling mixtures. After the addition of methyl alcohol, refractionation yielded azeotropic mixtures of alcohol and the hexanes, all of which boiled below 58.7° C. The following isomers were separated: 2,3-dimethylbutane, 2- and 3-methylpentanes, and n-hexane but no 2,2-dimethylbutane. Later they isolated n-heptane[72] (boiling at 98.4° C.), n-decane[73] (boiling at 174.0° C.), 2-methylhexane[74] (boiling at 89.67° C.), and showed the probable presence of 2,2-dimethylpentane.[75]

Leslie and Schicktanz[76] separated pure n-octane from a fraction (boiling point, 100°-130° C.) of the same crude from Oklahoma, by a series of fractional distillations followed by fractional crystallizations at low temperatures. Treatment with chlorosulphonic acid was employed to obtain the purest product. Leslie[77] also isolated 2-methylheptane (boiling point, 117.2° C.) by crystallization from liquid methane. By fractionation of a Pennsylvania straight-run gasoline, Tongberg and Fenske[78] isolated 2-methylpentane (boiling at 60.3° C.), n-heptane (boiling at 98.4° C.), methylcyclohexane (boiling at 100.8°-100.9° C.), and n-octane (boiling at 125.2° C.).

The use of chlorosulphonic acid in the purification of normal paraffins is effective because hydrocarbons containing the grouping R_3CH are rapidly attacked whereas normal hydrocarbons (and also cyclohexane) are only slowly affected by the reagent.[79] Shepard, Henne, and Midgley[80] also applied this reagent to the isolation of normal paraffins in a pure state from closely cut gasoline fractions. A gasoline of about 70 per cent normal paraffin content was distilled into fractions which roughly represented the normal homologues. The fractions were then treated with chlorosulphonic acid until no further change of density occurred, and were subsequently redistilled through a spiral fractionating column with an efficient dephlegmator. In this way the eight normal paraffins from pentane to dodecane were obtained in a satisfactory state of purity, the freezing range for each fraction being less than 0.1° C.

Table 7 contains data for a number of paraffin fractions which have been isolated by fractional distillation from various gasolines.[80a] Some of these fractions approximate very closely the physical properties of the corresponding pure hydrocarbon.

The naphthene hydrocarbons of the gasoline fraction of petroleum consist mainly, if not entirely, of cyclopentane and cyclohexane homologues. It is possible that hydrocarbons possessing monocyclic carbon ring systems with other than 5 or 6 carbon atoms are also present to some extent, but the evidence adduced of their presence is not convincing. Midgley [81] was reported to have isolated a dimethylcyclobutane from a gasoline fraction of Californian petroleum, and Markownikow [82] obtained evidence of the presence of cycloheptane in a fraction (boiling at 115° to 120° C.) of a Caucasian petroleum. A considerable number of cyclopentane and cyclohexane hydrocarbons have been more or less positively identified in various gasoline fractions of crude petroleums. Cyclopentane itself was found by Markownikow [83] in the 48° to 57° C. fraction of a Caucasian petroleum, and by Young [84] in an American petroleum fraction. Cyclopentane appears to be present in many petroleums and has even been found in the highly paraffinic gasoline from Cabin Creek.[85] Methylcyclopentane has been found in Caucasian,[86] American,[87] Rumanian [88] and Japanese [89] petroleums. Hicks-Bruun and Bruun [90] isolated a pure specimen of methylcyclopentane from a fraction of a Mid-Continent petroleum by nitration of the accompanying benzene followed by distillation and fractional melting. A 1,1-dimethylcyclopentane (boiling at 87.5° C.) was later identified by them in this same petroleum.[91]

The presence of cyclohexane in a sample of American petroleum was demonstrated by Young.[92] As early as 1880, however, Beilstein and Kurbatow [93] showed that the lower fractions of Russian petroleum contain non-olefinic hydrocarbons of the formula C_nH_{2n}. Baeyer's synthesis of cyclohexane [94] led to the identification of this hydrocarbon (boiling point, 80° C.) in a Baku naphtha.[95] At about the same time a hydrocarbon boiling at 72° C. was isolated and proved to be the isomeric methylcyclopentane.[96] Fortey [97] isolated what was at first considered to be pure cyclohexane (boiling point, 80.8° C.) from a sample of Galician petroleum. It was afterwards found, however, that it could be partially

but not completely frozen. In all probability a small amount of a heptane was present which could not be separated by fractional distillation, but fractional crystallization resulted in the separation of pure cyclohexane[98] boiling at 80.85° C. This hydrocarbon has also been isolated from certain fractions (boiling about 80° C.) of Mid-Continent crude petroleum.[99] Bruun and Hicks-Bruun[100] later isolated and determined methylcyclohexane (boiling point, 100.8° C.) in this petroleum.

A number of cyclohexane homologues have been identified in fractions of various crudes. These include methylcyclohexane,[101] 1,2- and 1,3-dimethylcyclohexanes,[102] 1,2,4-trimethylcyclohexane[103] and two isomeric decanaphthenes[104] (probably dimethylethylcyclohexanes). Skowronski[105] made a study of the lower cyclohexanes in a petroleum from Tustanowic (Galicia). The crude petroleum was carefully fractionated and the fractions were purified with cold fuming sulphuric acid. The cyclohexane hydrocarbons present in the residual oil were then oxidized, by heating with iodine, to the corresponding benzene hydrocarbons which were identified as their bromo-derivatives. Besides the above cyclohexane homologues, the presence of 1,4-dimethylcyclohexane was definitely established. Octa-, nona- and decanaphthenes have been found in Japanese petroleums.[106] Bicyclic naphthenes, chiefly derivatives of hydrogenated naphthalenes, have been found in various gasolines, for example the decahydronaphthalene isolated by Ross and Leather[107] from Borneo petroleum. The bicyclic hydrocarbons $C_{10}H_{18}$ and $C_{13}H_{24}$ isolated by Coates[108] from the Jennings, La., crude were probably dicyclopentyl and its methylated derivatives.

The actual proportions of aromatic hydrocarbons in most petroleums are usually relatively small.[109] On account of their greater ease of identification (since they can be readily converted to characteristic crystalline derivatives) the aromatic hydrocarbons have received much more attention than the naphthenes. In addition to the simple benzene homologues, more complicated polynuclear aromatic hydrocarbons (including naphthalene and its homologues) have also been identified.

Benzene and toluene are present in many crudes, notably in the gasoline from Koetei (Borneo) petroleum. Mabery[110] identified m- and p-xylenes in Ohio and Canadian crude petroleum. Tausz[111] showed that o-xylene and ethylbenzene also occur in many petroleums. According to Tausz, the relative proportions of the three xylenes and ethylbenzene (calculated on the total C_8 aromatic hydrocarbon content) in various petroleums are as given in Table 8.

Investigations of the aromatic hydrocarbons of Burma petroleum have been made by Mulany and Watson[112] and of Byoritsu (Formosa) crude by Kurihara.[113] The percentages of benzene, toluene, and xylenes in the fraction of the Byoritsu crude distilling up to 155° C. were 3.1 per cent, 20.2 per cent and 20.9 per cent of the distillate or 1 per cent, 8 per cent and 8 per cent of the crude, respectively. Besides benzene and toluene, m- and p-xylenes, mesitylene, and naphthalene were definitely identified in this crude.

TABLE 8.—*Per Cent of Total C_8 Aromatic Content.*

Petroleum	Ethylbenzene	o-Xylene	m-Xylene	p-Xylene
Rumania	26	24	42	17
Pennsylvania	13	36	47	4
California	16	20	56	8
Hannover	13	43	40	4
Borneo	16	10	62	12

Bruun, Leslie and Schicktanz[114] observed that all the fractions of an Oklahoma crude oil boiling from 90° to 112° C. contained toluene. The greatest concentration of this aromatic hydrocarbon was found in the fraction boiling between 107° and 108° C. Estimation of toluene by converting it to 2,4-dinitrotoluene indicated that it was present in the crude oil to the extent of 0.33 per cent. From this same petroleum were later isolated the three xylenes,[115] ethylbenzene[116] (boiling at 136.05° C.), mesitylene, pseudocumene, and hemimellitene.[117] A cyclic hydrocarbon, $C_{10}H_{16}$, melting at 268° C., to which was given the name adamantane, was separated from a Hodonin (Moravian) petroleum by Landa and Macháček.[118] According to Birch and Norris,[119] mesitylene and pseudocumene are probably the commonest aromatic constituents of liquid petroleums and usually occur together.

The hydrocarbons which have been isolated by investigators at the U. S. Bureau of Standards from a single sample of crude oil obtained from well No. 6 of the South Ponca field, Kay County, Oklahoma,[120] a typical Mid-Continent crude, are shown in Table 9.[121]

KEROSENE

The kerosenes obtained from American crudes follow the same general trend, as regards chemical characteristics, as gasolines. Eastern kerosenes are more paraffinic and those from California more aromatic. The identification of definite hydrocarbons, and even of definite classes of hydrocarbons, in kerosene fractions is a matter of great difficulty. As has been previously mentioned, because of the ease with which aromatic hydrocarbons may be segregated with liquid sulphur dioxide and because of their ready conversion into easily identifiable derivatives, our knowledge of the aromatic content of kerosenes is much more extensive than that of the other classes of hydrocarbons. In the large-scale refining of kerosenes by the Edeleanu process, which makes use of the preferential solvent action of liquid sulphur dioxide, the aromatic hydrocarbons are for the most part removed from the bulk of the kerosene. The sulphur dioxide extract is thus a valuable source of aromatic hydrocarbons offering commercial possibilities.

The sulphuric acid method of refining petroleum distillates also tends to remove the aromatic hydrocarbons in the form of the so-called "acid sludge." The aromatic hydrocarbons present in the acid sludge obtained by treating Persian kerosene with fuming sulphuric acid (20% SO_3) have been investigated by Birch and Norris.[122] The following hydrocarbons were definitely identified by the preparation of crystalline derivatives: toluene, m- and p-xylenes, mesitylene, pseudocumene, hemimellitene, p-ethyltoluene, an ethylxylene, a dimethylnaphthalene, and some indication of a trimethylnaphthalene.

---

[122] *J.C.S.*, 1926, 2545.

According to Mulany and Watson,[123] p-cymene is the most important aromatic constituent of Burma kerosene. The aromatic hydrocarbons present in Burma crude have also been studied by Carpenter[124] who found indications of the presence of hydrocarbons up to pentaethylbenzene (boiling point, 277° C.).

Bicyclic hydrocarbons of the aromatic and hydroaromatic type occur in many kerosenes. Mabery[125] isolated naphthalene from a fraction (boiling point, 220°-222° C.) of a California petroleum. The mono- and dimethyl derivatives of naphthalene were found by Jones and Wootton[126] in a Borneo petroleum, which contained 6 to 7 per cent of naphthalene hydrocarbons. Naphthalene, 2-methylnaphthalene and 2,6-dimethylnaphthalene have been isolated from the kerosene acid sludge of a Formosa crude.[127] Hydrocarbons of the formulas $C_{12}H_{18}$, $C_{14}H_{20}$, $C_{13}H_{18}$, and $C_{14}H_{18}$ were isolated by Wagner[128] from the sulphur dioxide extract of an Oklahoma kerosene. These were considered to be partly hydrogenated substituted naphthalenes. The part of the kerosene insoluble in liquid sulphur dioxide was said to be practically unaffected by sulphuric acid (specific gravity, 1.84) and consisted essentially of members of the cyclohexane series.

Of the non-aromatic hydrocarbons of kerosene fractions of petroleum, comparatively little definite information is available. There is little doubt, however, that most kerosenes consist very largely of paraffins and cycloparaffins (cyclohexane and cyclopentane homologues), but the separation of pure chemical individuals of these series from kerosene fractions is almost impossible by ordinary fractionation methods. Incidentally, the influence of various hydrocarbons, especially the aromatics and olefins, on the light intensity of kerosenes is a subject of controversy.[129]

HIGHER FRACTIONS OF PETROLEUM

Knowledge of the chemical nature of the high-boiling hydrocarbon constituents of petroleum is also meager. This is not surprising in view of the extreme complexity of such hydrocarbon mixtures and the difficulty of distilling them without decomposition. For these reasons fundamental research on the chemical nature of the higher petroleum hydrocarbons has made but little progress despite much painstaking effort. Various attempts have been made to utilize selective solvent action for concentrating the hydrocarbons into fractions of particular types. Though theoretically this method is excellent, since it avoids conditions where decomposition and molecular rearrangements are likely to occur, it has not led to any definite results in practice. However, Mabery[130] employed, with some success, a mixture of ether and ethyl alcohol for effecting some separation of various high-boiling petroleum fractions.

A general characteristic of petroleum hydrocarbons as a class is that, though the lower-boiling fractions (gasolines and kerosenes) approximate the formulas C_nH_{2n+2} (paraffins) and C_nH_{2n} (naphthenes), the higher-boiling fractions consist of hydrocarbons much more deficient in hydrogen. Hydrocarbons having the approximate general formulas C_nH_{2n-12} to even C_nH_{2n-20} have been found in the highest fractions of some petroleums. The higher-boiling fractions from even those typically paraffinic crudes which yield gasolines and kerosenes consisting largely of paraffin hydrocarbons contain relatively small amounts of saturated hydrocarbons. Thus, the paraffin wax content of light lubricating oils seldom exceeds 6 per cent. No paraffins, other than those in the wax, have been identified in the lubricating fractions. Paraffin wax is produced commercially on a large scale by chilling light lubricant fractions of petroleum.[131] The commercial product ordinarily melts between 48° and 62° C. and consists largely of a mixture of hydrocarbons of 23 to 28 carbon atoms per molecule. The principal constituents of paraffin wax are the normal paraffin hydrocarbons, but in addition to these straight-chain compounds, other types of hydrocarbons, probably branched-chain paraffins or isoparaffins (rather than unsaturated or cyclic compounds) are present.[132] Buchler and Graves [133] found paraffins ranging from $C_{18}H_{38}$ to $C_{43}H_{88}$ in paraffin wax, slop wax, petrolatum, and rod wax. Besides the freely crystallizing varieties of paraffin wax, there are also so-called amorphous waxes, which are very troublesome to refiners. These amorphous waxes are regarded by some [134] as ordinary paraffins whose crystallization has been inhibited by the presence of colloidal impurities. Though the real nature of amorphous wax has not yet been elucidated, some evidence has been advanced to show that it probably consists of a mixture of branched-chain paraffins.[135] Nametkin and Nifontova,[136] from a study of the nitro-derivatives of a Grozny and an American paraffin wax, concluded that about 25 to 30 per cent of isoparaffins were present. The presence of naphthenic or unsaturated hydrocarbons in both crystalline and amorphous waxes is not definitely disproved though somewhat doubtful, in view of the evidence.

[130] *Ind. Eng. Chem.*, 1923, 15, 1233.

Ceresin, a purified form of ozokerite (mineral wax), presumably consists also of a mixture of paraffin hydrocarbons, probably mainly isoparaffins, of somewhat higher average molecular weight than those of paraffin wax. Marcusson [137] examined the distillation products of ceresin and found saturated hydrocarbons and olefins of low molecular weight but obtained no evidence of the presence of naphthenes. Shale oil is also a source of paraffin wax.[138]

The so-called vaseline (petrolatum or petroleum jelly), which is made by careful filtration of certain residual oils through decolorizing earth, possesses the colloidal characteristics of a gel. Mabery [139] found that the commercial product consisted of heavy oils which form the high-boiling portion of Pennsylvania petroleum, hydrocarbons of the series C_nH_{2n}, C_nH_{2n-2} and C_nH_{2n-4}, together with solid paraffin hydrocarbons.

Little is known about the constitution of the hydrocarbons of the lubricating oil range. It is almost certain that normal or straight-chain paraffin hydrocarbons are absent, or present only in small amounts. Kyropoulos [140] considered the typical lubricating fractions from Pennsylvania crude oils to consist largely of isoparaffins, and Davis and McAllister[140a] believe that this type of oil consists essentially of a combination of naphthene rings and paraffin chains. The simple naphthenes, apparently homologues of cyclohexane and cyclopentane, together with polynaphthenes (fully saturated polycyclic hydrocarbons), have been reported by Seyer and Huggett[141] to be present in a lubricating fraction of Peruvian petroleum. Mabery,[142] in a comprehensive study of the lubricating fractions of various crudes, did not find the simple naphthenes in any of the oils examined. He concluded that the most highly saturated hydrocarbons in American petroleum which exhibit lubricating properties belong to the series C_nH_{2n-2}, and the hydrocarbons comprising the main bulk of the light and medium-heavy lubricants are of the series C_nH_{2n-4}. The heavier grades of lubricants conform to the formula C_nH_{2n-8}, but hydrocarbons even more deficient in hydrogen (series C_nH_{2n-10}, C_nH_{2n-12}, C_nH_{2n-14}, C_nH_{2n-16}, and C_nH_{2n-18}) were also encountered. Charitschkoff[143] found a hydrocarbon, $C_{19}H_{38}$, and several of the series C_nH_{2n-2} ($C_{10}H_{36}$, $C_{21}H_{40}$, $C_{22}H_{42}$, $C_{24}H_{46}$ and $C_{35}H_{68}$) in Groszny petroleum. Much of what has been written concerning the chemical structures of these hydrocarbons is purely conjectural. It is significant, however, that in the examination of lubricating fractions from various crudes, Mabery found fractions of the same general formula (e.g., C_nH_{2n-8}) which differed widely in specific gravity, a fact which may be ascribed to paraffin-chains attached to more or less complex ring structures of aromatic and naphthenic character.

---

[131] Following this chilling process and separation of the oil and wax by pressing, the wax is generally submitted to a "sweating" operation in which the major portion of the entrained oil is removed. Allibone (British Patent 358,668, 1930; assigned to Burmah Oil Co., Ltd.; *Brit. Chem. Abs.* **B**, 1932, 11) has suggested that following the sweating operation the wax be distilled at low pressures (2 to 10 mm.) in order to produce products of more clearly defined melting points. For a method of determining the quantity of wax in petroleum products, see Tormey, *Analyst,* 1931, **20** (6), 15; *Brit. Chem. Abs.* **B**, 1932, 376.

Not only the specific gravity, but the viscosity of hydrocarbons as well, is dependent on the chemical structure. Hugel[144] observed that, for hydrocarbons of the same molecular weight, the viscosity of cyclic hydrocarbons is greater than that of paraffins. Introduction of side chains, as well as unsaturation, had little effect on the viscosity of acyclic hydrocarbons. With cyclic hydrocarbons, however, the introduction of side chains, particularly methyl groups, had a specific effect though not always in the same direction. The viscosity of unsaturated compounds was increased by saturation.

Though it has often been suggested that unsaturated hydrocarbons are present in lubricating fractions,[145] it is more probable that the main constituents of these oils are polynuclear naphthenes, some of which, on account of their ability to undergo nuclear fission under certain conditions, simulate the reactions of unsaturated compounds.

NON-HYDROCARBON CONSTITUENTS OF PETROLEUM

Crude petroleums often contain appreciable proportions of organic substances other than hydrocarbons. Organic carboxylic acids are present in a number of crudes and are discussed in Chapter 48 under the generic designation, naphthenic acids. Phenolic compounds have been found in some crudes.[146] The asphaltic constituents of crude petroleum consist essentially of highly condensed oxygenated compounds. The sulphur-containing compounds comprise not only hydrogen sulphide and its organic derivatives (such as mercaptans and disulphides) but also more complicated sulphur compounds, including thiophene and its derivatives.[147] Some crudes even contain relatively large amounts of elemental sulphur. Organic bases, which include complex nitrogen compounds, also occur in petroleum. Interest in these nitrogen compounds has been revived, largely as a result of a series of investigations of their properties and constitution. A detailed account of these substances is to be found in Chapter 35.

[146] See Story and Snow, *Ind. Eng. Chem.*, 1928, **20**, 359. Phenols in shale oil have been determined by Lazar, *Chem.-Ztg.*, 1921, **45**, 197; Waterman, deJong and Tulleners, *J. Inst. Pet. Tech.*, 1932, **18**. 183. The separation of phenols from hydrocarbons is described by I. G. Farbenindustrie A.-G. (French Patent 739,742, 1932; *Chem. Abs.*, 1933, **27**, 2293), and by Masters (U. S. Patent 1,817,444, Aug. 4, 1931; assigned to Elko Chemical Co.; *Brit. Chem. Abs.* **B**, 1933, 218).

The presence of inorganic matter in petroleum is of interest in connection with various theories of its origin.[148] The percentage of ash obtained by ignition of various crude petroleums varies widely but appears to be highest with the more asphaltic crudes, such as those of Mexico. Analyses of the ash of crudes have been made by Ramsay,[149] Thomas,[150] and Shirey.[151] Both vanadium and nickel occur in petroleum ash. Although nickel apparently occurs to some extent in the ash of all crudes, vanadium appears to associate itself more strictly with those of asphaltic nature. A vanadium pentoxide content of as high as 45 per cent has been reported in the ash from a Venezuela petroleum.[152] Several processes have been developed for the extraction of vanadium from petroleum ash.[153] Table 10 shows the vanadium and nickel content of the ash of various asphaltic crude petroleums:

TABLE 10.—*Vanadium and Nickel Content of Petroleum Ash.*

Source	Base	Per Cent of Ash	
		V_2O_5	NiO
Persia	1.17 asphaltum	5.03	2.70
Oklahoma	asphalt	22.14	5.89
Kansas	——	0.44	0.57
Texas Panhandle	——	1.43	1.52
Mid-Continent	——	trace	0.52
Wyoming	——	trace	0.33

The occurrence of vanadium in petroleum ash has been discussed also by Porter [154] and by DeGolyer.[155]

PURE HYDROCARBONS FROM PETROLEUM

The separation of pure hydrocarbons from petroleum is the initial stage in the chemical utilization of such hydrocarbons. Since, in general, synthetic chemicals must conform to rigid standards of purity and chemical homogeneity, it is ordinarily essential to start with pure compounds as raw materials. Although industrial distillation apparatus when specially designed for a particular purpose is much more efficient than laboratory equipment, yet the large-scale separation of individual hydrocarbons above heptane in the paraffin series, or above cyclohexane in the cycloparaffin series, in a degree of purity comparable with that of toluene for synthetic purposes, is a matter of great difficulty by distillation alone.[155a]

As has been indicated previously, it is a matter of comparative ease, both on a large scale and in the laboratory,[156] to isolate the lower paraffin hydrocarbons (methane, ethane, propane, and the two butanes) from natural gas. This facility is to be attributed to the relatively great differences in the boiling points of these hydrocarbons, or in other words, to the great differences in their vapor pressures at any particular temperature. The difference between the boiling points of methane and propane at atmospheric pressure is fully 70° C. Propane boils 45° C. higher than ethane, and n-butane about 44° C. above propane. With increasing molecular weight, however, the differences between the vapor pressures of the members of the series decreases, so that increasing difficulty is experienced in effecting a separation. Moreover, the existence of an increasing number of isomers,[157] as has been mentioned previously, further complicates the matter.

Pure paraffin hydrocarbons from methane to butane (also isobutane) are readily obtained by careful pressure-fractionation of wet natural gas. The principles of such natural-gas fractionation have been described by Beall [158] and need not be discussed here. Relatively pure propane and a mixture of the two butanes, as previously stated, are now available in liquid form in cylinders for fuel purposes. The isolation of pure methane from coal-distillation gases may also be readily effected but in this case the problem is complicated by the presence of gaseous olefins, particularly ethylene. Adsorption on charcoal can be applied for further purification—for example, for separating higher hydrocarbons from methane.[158a]

Of the three isomeric pentanes, all of which are present in natural-gas gasoline, tetramethylmethane is the least abundant. Nevertheless, it is not a very difficult matter to obtain it pure by careful fractionation and in 1925 several hundred gallons of the hydrocarbon (boiling point, 9.5° C.) were isolated by this method.[159] Similarly, the recovery of a substantially pure mixture of n-pentane (boiling point, 36° C.) and isopentane (boiling point, 28° C.) was effected by fractional distillation. It is not quite as easy to obtain n-pentane and isopentane separately but with efficient modern equipment the large-scale separation of the pure isomers has been successfully accomplished.

No attempt has been made to produce paraffins higher than n-pentane on a large scale, but diisopropyl (boiling point, 58° C.) and dimethylpropylmethane

---

[155a] Piper, Chibnall, Hopkins, Pollard, Smith and Williams (*Biochem. J.*, 1931, 25, 2072; *Chem. Abs.*, 1932, 26, 2696) synthesized some highly purified paraffins from $C_{24}H_{50}$ to $C_{36}H_{74}$ and offered suggestions to aid in the fractionation and identification of the paraffins of petroleum.

[156] Separation of hydrocarbons by precise fractional-distillation analysis is discussed in Chapter 49; see Podbielniak, *Ind. Eng. Chem., Anal. Ed.*, 1931, 3, 177.

[157] The following figures (Henze and Blair, *J.A.C.S.*, 1931, 53, 3077) show how rapidly the number of isomeric paraffin hydrocarbons increases with increasing carbon content:

Carbon Atoms	*Isomers*	*Carbon Atoms*	*Isomers*
1	1	7	9
2	1	8	18
3	1	10	75
4	2	12	355
5	3	14	1858
6	5	16	10359

No simple or direct relationship appears to exist between the number of isomeric paraffin hydrocarbons and the number of carbon atoms in the molecule.

Blair and Henze made calculations also for the number of non-stereoisomeric and stereoisomeric paraffin hydrocarbons (*J.A.C.S.*, 1932, 54, 1538), the number of structurally isomeric alcohols of the methanol series (*J.A.C.S.*, 1931, 53, 3042), the stereo- and non-stereoisomeric monosubstitution products of the paraffins (*J.A.C.S.*, 1932, 54, 1098), and the number of isomeric hydrocarbons of the acetylene series (Coffman, Blair and Henze, *J.A.C.S.*, 1933, 55, 252). Perry (*J.A.C.S.*, 1932, 54, 2918) calculated the number of certain homologues of methane and methyl alcohol.

[158] *Refiner*, 1931, 10 (1), 110; *Chem. Abs.*, 1931, 25, 1360. For fractional liquefaction of natural gas, see Claude and Jordan, U. S. Patent 1,497,546, June 10, 1924; *Chem. Abs.*, 1924, 18, 2421; Dumars, U. S. Patent 1,747,761, Feb. 18, 1930; *Chem. Abs.*, 1930, 24, 1726.

[158a] Storch and Golden, *J.A.C.S.*, 1932, 54, 4662.

[159] Ayres, *Ind. Eng. Chem.*, 1929, 21, 899.

(boiling point, 62° C.) could probably be isolated in a relatively pure condition if a demand for these hydrocarbons were assured.

Investigations have shown that normal paraffins may be separated from the more reactive branched-chain isomers with certain chemical reagents, such as chlorosulphonic acid.[160] Although this is undoubtedly of value in the laboratory, its applicability to large-scale work is doubtful. High homologues of methane can be purified by various procedures, for example, by steam distillation;[161] by fractional distillation in high vacuum, which has been used for separating mixtures of eicosane and triacontane, and tetracosane and triacontane;[162] or by crystallization from liquid hydrocarbons, the method used by Leslie[163] for the isolation of 2-methylheptane from petroleum.

The isolation of simple mononaphthenes in a state of high purity has never been attempted on a large scale, but comparatively pure cyclohexane, cyclopentane and their immediate homologues have been obtained in the laboratory from various crude petroleums. Since, however, the few industrially valuable derivatives of cyclohexane can readily be prepared from the corresponding benzene derivatives, it is somewhat unlikely that the mononaphthenes of petroleum, containing a six-membered carbon ring system, will be utilized as raw materials for chemical synthesis. The aromatization of such cyclohexanes can be effected by thermal dehydrogenation.

The aromatic hydrocarbons present in gasoline and kerosene fractions of petroleum are of considerable interest from the standpoint of chemical synthesis. Although coal tar is a source of aromatic substances, the benzene homologues found in such tars have a tendency to conform to certain definite configurations.[163a] Thus, of the benzene homologues present in coal tar, the m-disubstituted and the 1,3,5-trisubstituted types predominate. It is therefore more than probable that aromatic hydrocarbons of petroleum will be used as a source of benzene homologues which do not occur, or which are present only in small proportions, in coal tar. Bicyclic and polycyclic aromatic derivatives also occur in petroleum but are of less interest at present from a technical point of view since they are abundant in coal tar.

For the separation of aromatic hydrocarbons from petroleum distillates, fractionation is usually inadequate if pure products are desired. However, fractionation of some gasolines rich in aromatics yields fairly pure benzene and toluene. To isolate the higher aromatics it is advantageous to adopt a method of partially concentrating the aromatic hydrocarbons from the paraffins and naphthenes. On account of the greater chemical reactivity of the aromatic hydrocarbons as a class, several such methods are known. Selective solvent action, for example, can be employed.[163b] Both sulphuric acid and liquid sulphur dioxide exert a selective solvent action on the aromatic hydrocarbons of gasolines and kerosenes. The latter solvent is used in the well-known Edeleanu process[164] for the removal of aromatic hydrocarbons from kerosene distillates. Edeleanu's investigations were started with a Rumanian kerosene distillate containing 25 per cent of aromatics, the presence of which caused the kerosene to burn with a sooty flame. The removal of this large proportion of aromatic hydrocarbons required fuming sulphuric acid and entailed high refining losses. It was found that liquid sulphur dioxide at —10° C. extracted the aromatics with smaller refining losses. Two liquid layers are formed, the upper (having a specific gravity of 0.9 to 1.0) consisting of the refined oil saturated with sulphur dioxide, and the lower (with a specific gravity of 1.3 to 1.4), a solution of the extract in sulphur dioxide. The two layers are easily separated and the sulphur dioxide can be evaporated at a temperature low enough to avoid any considerable loss of hydrocarbons. This Edeleanu extract is a possible fruitful source of aromatic hydrocarbons for chemical synthesis.

Sulphuric acid exerts a preferential solvent action for aromatic hydrocarbons and many sulphur compounds. Thus, Birch and Norris,[165] on treating 5000 gallons of soda-washed Persian kerosene with 0.75 per cent by volume of fuming sulphuric acid (20% SO_3) for 45 minutes, obtained a considerable amount of acid tar. After settling, the tar was allowed to run into water and about 55 gallons of a dark reddish-brown, highly sulphurous oil separated. The separated oil was found to consist of the sulphur compounds originally present in the kerosene and those formed by reaction with the acid, together with a complex mixture of aromatic hydrocarbons from which was separated a number of pure hydrocarbons of the benzene and naphthalene series.[166]

Other organic liquids also exert a preferential solvent action on the aromatic hydrocarbons of gasolines and kerosenes. Göhre[167] suggested several solvents for the purpose. Levulinic acid, which can be used at ordinary temperatures and is readily extracted with water, gives theoretical results for the aromatic content of oils containing up to 90 per cent of these constituents. Phenylhydrazine is satisfactory for the extraction of aromatics from various oils but not from low-boiling fractions. Glycol monoacetate in the proportion of 3 parts of solvent to 1 of oil gives reliable results at ordinary temperatures for light oils and oils of medium viscosity. Furfuraldehyde in the proportion of 1 : 1 at —10° C. is a solvent for extracting all oils. Other solvents which have been proposed for removing aromatics from gasoline fractions include dimethyl sulphate,[168] diethyl sulphate,[169] a mixture of sulphoacetic acid and acetic anhydride,[170] nitroso- or cyano-substituted aliphatic hydrocarbons (for example, methyl nitrite),[171] and selenium oxychloride.[172]

In a few particular cases it is not necessary to concentrate the aromatic hydrocarbons. The oil is first fractionated to yield a narrow cut relatively rich in the aromatic hydrocarbon and this is then submitted to chemical treatment to yield the desired product. This method has been applied to toluene-containing frac-

[172] Lenher, U. S. Patent 1,473,350, Nov. 6, 1923.

tions of gasoline rich in aromatics, for example, Borneo (Koetei) petroleum. Nitration of such fractions can be made to yield TNT.[173] The oxidation of toluene-containing petroleum distillates for the production of benzaldehyde or benzoic acid has been investigated by a number of workers (see Chapter 41). In general, however, for the production of chemical derivatives of aromatic hydrocarbons it is advantageous to start with materials as pure as possible, since the presence of aliphatic hydrocarbons frequently leads to great technical difficulties in the isolation and subsequent purification of the product.

The separation of the non-aromatic hydrocarbons of gasolines and kerosenes with various solvents has been attempted from time to time but without much success. A method of concentrating naphthenes and paraffins in gasoline fractions by differential solubility in liquid sulphur dioxide was described by Egloff, Morrell and Moore,[174] but Seyer and Gill [175] examined the solubility relationships underlying this method and found them unfavorable. Ferris [176] proposed a method for the partial concentration of paraffins and naphthenes in mineral oils with nitrobenzene, which is said to exert a greater solvent action on the naphthenic hydrocarbons. Other solvents which have been suggested for the separation of paraffin and naphthene constituents of mineral oils [177] include phenol,[178] cresylic or wood-tar acids,[179] benzaldehyde,[180] benzonitrile,[181] phenyl acetate or organic thiocyanates,[182] furfuralcohol,[183] and β,β'-dichloroethyl ether (Chlorex).[183a] Attempts have been made to separate naphthenes from paraffins by chemical treatment under such conditions that only the former are attacked. Some of the chemical treatments which have been advocated include oxidation,[184] combination of naphthenes with benzoyl chloride in the presence of aluminum chloride,[185] and the action of fuming nitric acid.[186] It is extremely likely, however, that although the normal paraffins may be unaffected by such treatments, the relatively more reactive isoparaffins will be attacked as well as the naphthenes.

THE ORIGIN OF PETROLEUM

In a work of this character it is unnecessary to consider fully the various theories which have been advanced to explain the origin of petroleum. Many of the older theories, including the inorganic (carbide) theory, have been abandoned, the evidence for an organic origin for petroleum appearing now to be almost conclusive. In addition to the geological evidence, the organic theory is supported by the chemical nature of petroleum, more especially by the presence of optically active substances, naphthenic acids, and sulphur and nitrogen compounds.[186a] Moreover, the absence of carbon monoxide, hydrogen, and olefins in natural gas and of unsaturated compounds in petroleum, as mentioned previously, appears to indicate that low-temperature processes are alone responsible. The presence of aromatic hydrocarbons in petroleum does not necessarily indicate a high-temperature synthesis since the existence of these hydrocarbons can also be explained by disproportionation [188] reactions at low temperature. The possibility that synthetic processes as a result of the action of alpha-radiation from radioactive minerals are partly responsible for petroleum formation, as suggested by Lind,[187] is rendered doubtful by the composition of petroleum and natural gas.[188]

Although an organic origin for petroleum is fully indicated by the evidence available, there is no general agreement as to the mechanism and the raw materials of the process. Anaerobic fermentation and destructive distillation of both animal and vegetable remains have been suggested from time to time.[189] Destructive distillation would probably yield hydrogen and carbon monoxide, which are not present in any gaseous petroleums (the unsaturated hydrocarbons, simultaneously produced during thermal dissociation processes, could be assumed to have polymerized to aromatic and saturated cyclic hydrocarbons). Oil and bituminous products resulting from the prolonged acid hydrolysis of an aqueous extract of seaweed or algae, as well as from the acid hydrolysis of sugars, calcium salts of ethereal sulphonic acids, or decomposition products of algae [190] would offer another explanation. On the whole, an anaerobic fermentation of organic material appears to be favored as the most likely mode of formation. The optical activity of some petroleums (possibly derived from cholesterol,[191] phytosterols, terpenes,[192] resins or proteins), as well as the presence of nitrogen compounds, serves in part to substantiate the fermentation theory.[193] It seems likely, however, that the several varieties of crude petroleums have been produced by somewhat different processes and from other raw materials. In some cases, the chemical character of the crude lends credence to the supposition that filtration through certain strata has resulted in a gradual separation of the more fluid and volatile hydrocarbons from the heavier and less volatile fractions. The latter would tend to be retained or adsorbed by the strata through which filtration had taken place. Undoubtedly such migration processes with attendant filtration and adsorption, would play an important rôle in determining the physical and chemical characteristics of crude petroleums.

Chapter 2

Thermal Decomposition of Hydrocarbons

The term thermal decomposition, or pyrolysis, embraces all those numerous and varied reactions which are brought about by the action of heat alone. Applied to hydrocarbons this not only involves a degradation of the molecule with the production of substances of lower molecular complexity, but must also include the frequent synthesis of more complicated molecules. Although the thermal decomposition of hydrocarbons has been studied for more than a century by many investigators, our knowledge of the processes involved and numerous products formed is still unfortunately very incomplete. Only the simpler hydrocarbons have been carefully studied and very little is known definitely of the corresponding behavior of the higher hydrocarbons.

The reasons for this lack of information about such reactions can be readily understood. The difficulty of preparing all but the simpler hydrocarbons as pure chemical individuals has proved a formidable obstacle, and the thermal decomposition of hydrocarbons generally gives rise to such a wide variety of products that their examination severely tests the ingenuity of even the most skilled investigators. Moreover, analytical methods for examining the complex gaseous and liquid mixtures produced were, until recently at any rate, simply not available. In particular, the methods of isolating and identifying olefin hydrocarbons are still most unsatisfactory. For such reasons as these, much of the work of the older investigators is marred by inaccuracies, and until recently there appeared to be an incomplete appreciation of the importance of numerous factors which exert a profound effect on the course and extent of the decomposition. It is now generally recognized that the most important factors to be considered in this regard are: temperature, duration of heating and area of heating surfaces, composition of heating surfaces, catalytic effects and pressure.

The thermal reactions of hydrocarbons were largely studied in the past from the point of view of their importance in the manufacture of coal gas, oil gas and carbureted water gas. At the present time, however, interest in these thermal processes lies in two principal directions, gasoline production and chemical synthesis. The enormous growth of commercial "cracking" operations, in which high-boiling petroleum fractions are degraded to yield quantities of low-boiling hydrocarbons, has made it possible to augment the world's supply of gasoline to meet the ever-growing demand for that product and thus to contribute vastly to the welfare of civilization. The by-products of the cracking process, more especially the cracking gas, are assuming an important position as suitable raw materials for chemical synthesis, and herein lie the vast potentialities of thermal decomposition processes. Recent researches have shown that pyrolysis is flexible and can be controlled to produce a variety of substances, especially appropriate as intermediates in the production of synthetic products. In other words, thermal decomposition is the link between relatively unreactive hydrocarbons present in petroleum and highly reactive substances useful as the bases of chemical synthesis.

In the following pages will be discussed the thermal decomposition of individual members of the four well-known series of hydrocarbons, namely paraffins, olefins, cyclic non-benzenoid hydrocarbons (naphthenes) and aromatics.[1] The reactions of each class will be summarized and the reaction mechanisms proposed will be outlined, some comparison being made with results of thermodynamic calculations. As catalysts influence greatly the course of such thermal reactions, these will also receive attention.

METHANE

As early as 1808, Dalton and Henry[2] found that when methane was repeatedly subjected to electric sparks or passed over an electrically heated platinum wire, or through a red-hot tube, it was converted, with deposition of carbon, into two volumes of pure hydrogen. The simultaneous formation of acetylene and olefins in the decomposition of methane by the action of heat or of electric sparks, was observed later by Berthelot,[3] who conducted methane through a porcelain tube heated to dull redness. He also observed the formation of small proportions of benzene and naphthalene.

Bone and Coward[4] studied the thermal decomposition of methane, ethane, ethylene and acetylene, and noticed that time of heating had a pronounced effect upon the yield and type of products. They reached the following conclusions with regard to the decomposition of methane in the presence of porcelain at temperatures between 500° and 1200° C.:

(1) Methane is the most stable of the hydrocarbons considered. It is always a principal product of the decomposition of the other three, especially above 800° C.

(2) It decomposes directly into carbon and hydrogen and the process, which is probably reversible at all temperatures, is chiefly a surface phenomenon.

(3) In the decomposition of methane, the formation of traces of acetylene and olefins can be detected only as long as the methane concentration exceeds 60 per cent. At low methane concentrations the gas continues to be resolved into its elements.

The effect of pressure on the decomposition of methane has been investigated by Warren.[5] Increase of pressure from 2 to 10 atmospheres decreased the yield of unsaturated hydrocarbons without influencing that of hydrogen, but at higher pressures the hydrogen decreased. Pressures below 1 atmosphere had little effect on either the hydrogen or unsaturated hydrocarbon yield.

The decomposition of methane in the presence of metallic magnesium was reported by Novak,[6] and Kusnetzov[7] studied the action of finely divided aluminum. The products found consisted solely of hydrogen and carbon (either free or combined as carbides).

That the decomposition of methane was a reversible reaction, $CH_4 \rightleftarrows C + 2H_2$, was demonstrated by Mayer and Altmayer.[8] They investigated this equilibrium from both directions at atmospheric pressure and at varying temperatures, with nickel, cobalt, and iron as catalysts. Their equilibrium values from 600° to 850° C. are here reproduced:

---

Temp. ° C.	Per Cent CH_4	Per Cent H_2	Temp. ° C.	Per Cent CH_4	Per Cent H_2
600	31.68	68.32	750	6.08	93.92
650	19.03	80.97	800	4.41	95.59
700	11.07	88.93	850	1.59	98.41

Slater[9] observed that the physical and chemical nature, as well as the area, of the heating surface had a pronounced effect on the rate of decomposition of methane into its elements. The rate of decomposition of methane in an unpacked tube was determined. By packing the same tube with silica, magnesia, alumina, or baryta, this rate of decomposition was decreased, but it was accelerated by packing with such materials as lime, copper, carborundum, graphite, charcoal, or iron. Cantelo[10] examined the methane equilibrium both theoretically and experimentally. From a thermodynamic standpoint, under conditions of equilibrium, he found that only negligible quantities of higher hydrocarbons would be formed. Later, Cantelo,[11] from theoretical as well as experimental considerations, found that the decomposition of all higher hydrocarbons resolves itself, under equilibrium conditions above 400° C., into the methane equilibrium, $CH_4 \rightleftarrows C + 2H_2$. Of the catalysts studied by Cantelo, one consisting of asbestos, nickel, and nickel oxide was found to be extremely active, almost complete decomposition[11a] being attained at 780° C.

The methane equilibrium has also been investigated by Scheffer, Dokkum, and Al,[12] who arrived at the following equilibrium concentrations at various temperatures:

Temp. ° C.	Per Cent CH_4	Per Cent H_2	Temp. ° C.	Per Cent CH_4	Per Cent H_2
450	66.0	34.0	650	21.0	79.0
500	53.4	46.6	700	14.5	85.5
550	41.0	59.0	800	6.8	93.2
600	29.9	70.1			

Schenk and his collaborators[13] quantitatively investigated the methane-hydrogen equilibrium in the presence of iron at temperatures from 350° to 880° C. and also in the presence of cobalt in the temperature range 310° to 740° C., their experimental results being in very good agreement with those of Scheffer, Dokkum, and Al. The occurrence of a second type of equilibrium, hitherto unsuspected, in which hydrogen, methane and a carbide of nickel, iron or cobalt are in equilibrium, has been definitely established by these investigators. Above 680° C., however, this equilibrium was not encountered.

For many years the main reaction occurring during the thermal decomposition of methane was considered to be that of direct decomposition into its elements. In 1928 Fischer[14] published the results of his work on the production of liquid hydrocarbons from methane by pyrolysis. Fischer believed that by shortening the heating period and controlling the rate of cooling, methane would not be decomposed directly into its elements but could be made to yield residues such as $\cdot CH_3$, $:CH_2$ and $\vdots CH$, which would then polymerize to higher hydrocarbons. In such a process catalytic materials which hastened the attainment of the $CH_4 \rightleftarrows C + 2H_2$ equilibrium, therefore, were to be avoided. To confirm this prediction Fischer passed pure methane at high gas speeds through porcelain and quartz tubes, heated to 1000°-1200° C., and observed the formation of considerable proportions of higher hydrocarbons. Acetylene was noticed in the reaction gas while the light oil obtained consisted of unsaturated hydrocarbons, benzene, toluene, and xylene, together with naphthalene. Some tar which contained higher aromatic hydrocarbons was also formed. In this pyrolysis, the formation of carbon and hydrogen was promoted by such substances as silicic acid, tungsten, molybdenum and tin but was retarded by iron and graphite. Fischer emphasized the importance of the time of heating in such reactions. When a heating period of ⅓ second was used, higher hydrocarbons were produced, while carbon and hydrogen only were obtained on increasing the duration of heating to 60 seconds.

The results obtained by Fischer were substantiated by Wheeler and Wood [15] and also by Stanley and Nash.[16] Wheeler and Wood found that a horizontal tube of quartz gave an optimum yield of benzene at 1050° C., and ethylene and butadiene were identified in the gaseous products of the reaction.[16a]

Stanley and Nash paid particular attention to the gaseous products of the reaction and found that comparatively long heating periods cause methane to decompose into its elements, this decomposition being increased by large heating surfaces and also by the use of such catalysts as iron and nickel. Porcelain, silica, and beryllia did not promote carbon formation. With short heating periods (as low as 0.4 second) at 1000°-1200° C., in the presence of silica, products similar to those described by Fischer were obtained. Thus at 1150° C. and 0.6 second heating duration, the yield of light oil and tar was 11 per cent of the methane used while acetylene and ethylene were present in the reaction gas to the extent of 8.8 per cent (based on methane); 6 per cent of methane had decomposed according to the equation $CH_4 \rightleftarrows C + 2H_2$. The yield of light oil was 4.8 per cent or 0.0281 gram per liter of methane.

A further extension of this work was carried out by Peters and Meyer,[17] who effected the conversion of methane into acetylene by subjecting it to temperatures of 1600°-3000° C. for extremely short periods. The heating elements were spirals of tungsten wire heated electrically, and alternatively, tubes of arc lamp carbon (2.5 mm. internal diameter). Heating periods as low as 0.0001 second were obtainable and in this way the conditions occurring in the electric arc were simulated in a purely thermal manner. Thus by passing a gas containing 89 per cent of methane through the tungsten spiral heated to about 2700° C. at such a rate that the heating period was 0.0003 second there was obtained a gas containing 6 per cent of acetylene. In another experiment substantially pure methane was subjected to a temperature of about 3000° C. in the tungsten spiral for a heating period of 0.0001 second and the reaction gas contained 15.4 per cent of acetylene, which corresponds to a yield of 325 grams of acetylene per cubic meter of initial gas. No benzene was found in the gases.

The mechanism of the conversion of methane into aromatic hydrocarbons has been discussed by Hague and Wheeler [18] in connection with their general theory of the thermal decomposition of normal paraffins, in which a very important

rôle is assigned to ethylene. These workers state: "The first member of the series, methane, requires special consideration. Although the absence of a C—C linkage causes its behavior to be different from that of the higher members, its decomposition point being about 200° C. higher than that of ethane, whereas there is but a 25° C. interval between the decomposition points of the others,[18a] yet liquid hydrocarbons in quantity are produced from methane, the formation of benzene being at its optimum over the range 1000° to 1100° C. As Bone and Coward[19] have shown, the main decomposition of methane is ultimately to carbon and hydrogen. At comparatively low temperatures, however, ethylene is formed. As with other paraffins, we regard this ethylene as the source, through butadiene, of the benzene and other aromatic hydrocarbons produced. The mechanism of the early decomposition may be expressed by $CH_3{\cdot}H \rightarrow {:}CH_2 + H{\cdot}H$, two of the $:CH_2$ residues, of fugitive existence as postulated by Bone and Coward, combining to form ethylene."

De Rudder and Biedermann[20] investigated the influence of temperature on the pyrolytic production of higher hydrocarbons from methane at various pressures. Below 1000° C. only traces of ethylene and no acetylene are formed, while at 1000° C. and at atmospheric pressure 2 per cent of ethylene and 0.5 per cent of acetylene can be obtained at appropriate rates of flow. At higher temperatures reduced pressures increased the yield of ethylene and acetylene. The maximum production of ethylene (4 per cent) occurred at 1200° C. and 100 mm. pressure, under which conditions 2.5 per cent of acetylene was simultaneously produced. At temperatures above 1300° C. no ethylene was found in the products of reaction and acetylene was formed in amounts increasing with rising temperature. The amounts of acetylene formed at 1300° C. under 100 mm., at 1400° C. under 50 mm., and at 1500° C. under 50 mm. pressure were 6.62 per cent, 10.5 per cent, and 14.5 per cent, respectively. According to these investigators, quartz, Marquardt porcelain and nickel exerted no catalytic influence, while the introduction of hydrogen chloride into the reacting gas also had no effect on the reaction. Acetylene formation was always accompanied by decomposition of some of the methane into carbon and hydrogen, the amount of decomposition increasing with increase in the volume of the pyrolysis chamber.

Important additional experimental evidence regarding the nature of the reactions occurring in high-temperature pyrolysis has been put forward by Wheeler and Wood.[21] Both static experiments in silica bulbs and stream experiments through heated tubes of different materials were carried out. The rapid initial decomposition of methane in silica vessels is chiefly a surface effect but the decomposition, they found, does not proceed to an equilibrium condition by surface action on account of the formation of a protective layer of adsorbed hydrogen, which leads to the establishment of a false state of equilibrium. The shortest periods of heating, in the stream experiments, favor the formation of compounds containing two carbon atoms in their molecules, whereas by increasing the duration of heating aromatic compounds are formed at the expense of these simple molecules. Butylene and butadiene were identified in the products of the reaction at 1050° C. but neither propylene nor acetylene could be detected. The use of an iron tube in stream experiments led to the complete decomposition of the methane to hydrogen and carbon, the latter being of a bulky gritty nature. On the other hand, both silica and chrome-iron tubes favored the formation of liquid hydrocarbons to an equal extent and the carbon formed in these cases was of a lustrous foil-like variety exerting no influence on the course of the pyrolysis. An increase in the area of silica exposed per unit volume of gas had no appreciable effect on the velocity or extent of pyrolysis. Wheeler and Wood concluded that the reactions which are important in stream experiments are those occurring throughout the volume of the gas (i.e., not on the surface) when the surface effect of the reaction vessel has been inhibited by an adsorbed hydrogen layer. In iron tubes this protective layer of adsorbed hydrogen is not formed and the surface decomposition of methane to carbon and hydrogen consequently takes place at the expense of the homogeneous reaction.

[18a] These figures refer to decomposition in the presence of inert materials such as silica or porcelain.

The important position assigned to ethylene by Hague and Wheeler [22] in the production of aromatic hydrocarbons will be discussed more fully later but it is important to note at this stage that no mention is made in their work of the relatively greater amounts of acetylene produced at higher temperatures. The possibility of acetylene being an intermediate in the production of aromatics from benzene must not be overlooked, this conclusion having been reached by Frolich, White and Dayton,[23] who studied the cracking of substantially pure methane in the presence of quartz at temperatures above 1000° C. (highest temperature 1150° C.) and at pressures from atmospheric down to 25 mm. They found that acetylene is the main primary product of cracking but has a marked tendency to polymerize into benzene and similar compounds, as well as to decompose further into carbon and hydrogen, so that it becomes necessary to employ exceedingly short times of contact. At the lowest time of contact employed, 0.6 second, about 11 per cent of the entering methane appeared in the exit gas as acetylene. At a time of contact of 0.6 second, however, there was considerable carbon deposition and polymerization and an acetylene yield of less than 5 per cent calculated on the methane. A reduction in pressure below atmospheric, even to as low a figure as 25 mm., did not materially affect the conversion of the methane into acetylene. Since the total amount of cracking was reduced by decreasing the pressure, however, the yield of acetylene calculated on the basis of the methane cracked was somewhat increased.

At present the question as to whether ethylene or acetylene is the intermediate in the production of aromatic substances in the pyrolysis of methane is still *sub judice*. The opinion of Frolich and his collaborators that acetylene is the probable intermediate is supported by the work of Holliday and Gooderham,[24] who concluded that the decomposition of methane in silica bulbs is mainly a homogeneous reaction which, at temperatures above 900° C., proceeds in two stages, namely:

$$(1)\quad 2CH_4 \longrightarrow C_2H_2 + 3H_2$$
$$(2)\quad C_2H_2 \longrightarrow 2C + H_2$$

According to Wheeler [25] the first stage of the decomposition of methane at 1000° C. in the presence of silica surfaces consists of a homogeneous bimolecular reaction in which ethylene, and probably not acetylene, is produced.

A study of the pyrolysis of methane from the viewpoint of the production of motor fuels from natural gas, led Smith, Grandone, and Rall [26] to conclude that ethylene is the dominant product in the initial stages of the pyrolysis, other hydrocarbons being formed subsequently. The addition of hydrogen decreased the yields of higher hydrocarbons. Both acetylene and ethylene occurred in the gaseous products of the pyrolysis, the production of these gases being increased by dilution of the reactants with either hydrogen or nitrogen. Padovani and Magaldi[27] found that in the pyrolysis of methane at 1000°-1250° C. in silica tubes dilution with hydrogen causes an increase in the production of unsaturated hydrocarbons at lower rates of flow though the reverse holds at higher rates of flow. This fact may help to explain the discrepancy between the reported results of other investigators on the influence of dilution with hydrogen. According to Padovani and Magaldi, the decomposition of methane is accelerated by filling the reaction tube with fragments of porous porcelain.

---

Kassel,[28] from his study of the thermal decomposition of methane in quartz bulbs at 700° to 850° C., however, suggested the following mechanism:

$$\begin{array}{lll}
(1) & CH_4 \rightleftharpoons & CH_2 + H_2 \\
(2) & CH_2 + CH_4 \rightleftharpoons & C_2H_6 \\
(3) & C_2H_6 \rightleftharpoons & C_2H_4 + H_2 \\
(4) & C_2H_4 \rightleftharpoons & C_2H_2 + H_2 \\
(5) & C_2H_2 \rightleftharpoons & 2C + H_2
\end{array}$$

He found that the presence of hydrogen very greatly retarded the methane decomposition. If hydrogen is present in sufficient quantities the decomposition rate varies directly with the square of the methane concentration and inversely with the cube of the hydrogen concentration.[29] This mechanism of Kassel accounts satisfactorily for the results obtained by Storch[30] on the decomposition of methane by carbon filaments. The latter observed ethane to be the earliest product of the thermal decomposition of methane. From the decomposition in a carbon-filament lamp immersed in liquid nitrogen as much as 95 per cent of the theoretical yield of ethane was obtained.

The main conclusions in regard to the thermal decomposition of methane are then as follows: Methane has great tendency to decompose into its elements but by shortening the heating time and employing temperatures above 1000° C. it is possible to prevent the further decomposition of the fugitive intermediate products of the reaction. At temperatures of 1000°-1200° C. under these conditions aromatic hydrocarbons as well as ethylene and acetylene are obtained, but at very high temperatures acetylene is the most important product. In the presence of materials such as iron and nickel it is impossible to stop the reaction at these intermediate stages and hydrogen and carbon only are formed.

ETHANE

Berthelot[31] considered that ethane on decomposition gave either ethylene and hydrogen, or acetylene, methane, and hydrogen as follows:

$$\begin{array}{lll}
C_2H_6 & \longrightarrow & C_2H_4 + H_2 \\
2C_2H_6 & \longrightarrow & 2CH_4 + C_2H_2 + H_2
\end{array}$$

The first comprehensive work was that of Bone and Coward,[32] who obtained evidence of the reactions:

$$C_2H_6 \longrightarrow C_2H_4 + H_2 \longrightarrow C + CH_4 + H_2$$

On continued heating large proportions of methane were found in the gas (i.e., after 6 hours heating at 675° C. the resulting gas had the composition C_2H_2, 1.9%; C_2H_4, 0.7%; C_2H_6, 2.0%; CH_4, 54.5%; and H_2, 40.9%). To explain the high proportions of methane, Bone and Coward assumed the existence of labile residues, $\vdots CH$, $:CH_2$, and $\cdot CH_3$. "These residues," as pointed out by Bone and Coward, "which can only have a very fugitive separate existence, may subsequently either (*a*) form $H_2C:CH_2$ and $HC\vdots CH$, as the result of encounters with other similar residues, or (*b*) break down directly into carbon and hydrogen, or (*c*) be directly 'hydrogenized' to methane in an atmosphere already rich in hydrogen." It must be noted, however, that the accumulation of methane and hydrogen in the reaction is to be expected from thermodynamic considerations only, since the decomposition of all hydrocarbons should ultimately resolve itself into the equilibrium $CH_4 \rightleftarrows C + 2H_2$. At 800° C. Bone and Coward found the decomposition of ethane to be rapid, thus necessitating the use of closed tubes. After one minute heating they obtained a gas having the composition C_2H_2, 1.9%; C_2H_4, 11.2%; C_2H_6, 17.9%; CH_4, 31.3%; and H_2, 37.7%. After one hour's heating only methane (63.8 per cent) and hydrogen (36.3 per cent) were found in the system. At higher temperatures the decomposition was even more rapid. Ethane was passed through a tube at a speed such that the gas would not remain in the reaction zone longer than one-half minute. As the time of heating at 1000° C. increased, the proportion of hydrogen formed increased and the methane content decreased. Bone and Coward obtained 4 per cent of condensable hydrocarbons, calculated on the ethane, at 1000° C.

Zanetti and Leslie[33] found that the chief products of the thermal decomposition of ethane-propane mixtures were ethylene, methane, propylene, higher olefins, hydrogen, and aromatic hydrocarbons. The proportion of unsaturated hydrocarbons was found to attain a maximum at 750° C., at which temperature the formation of aromatic hydrocarbons began. Furthermore, the presence of iron in the reaction chamber was observed to inhibit the formation of aromatic hydrocarbons and favor complete decomposition. The tar obtained was examined later by Zanetti and Egloff[34] and found to contain benzene, toluene, naphthalene, acenaphthene and other aromatic hydrocarbons. Davidson[35] used a variety of catalysts in the decomposition of ethane-propane mixtures. The metals iron, nickel and cobalt accelerated the formation of carbon and hydrogen and a temperature of 850° C. was found best for the formation of liquid hydrocarbons. Davidson was the first to suggest that butadiene is probably an intermediate in the formation of aromatic compounds and suggested the scheme:

$$CH_2{=}CH_2 + CH_2{=}CH_2 \longrightarrow CH_2{=}CHCH{=}CH_2 + H_2$$

The condensation of another molecule of ethylene with butadiene with elimination of more hydrogen could then yield benzene.

Williams-Gardner[36] suggested the following reactions for the decomposition of ethane at temperatures between 600° and 700° C.:

$$(1)\quad 2C_2H_6 \longrightarrow C_2H_4 + 2CH_4$$

$$(2)\quad C_2H_4 \longrightarrow 2C + 2H_2$$

---

[33] *J. Ind. Eng. Chem.*, 1916, **8**, 777.
[34] *J. Ind. Eng. Chem.*, 1917, **9**, 474.
[35] *J. Ind. Eng. Chem.*, 1918, **10**, 901.
[36] *Fuel*, 1925, **4**, 430.

At 900° C. he obtained a yield of 9.5 per cent of benzene and 17 per cent of total liquid hydrocarbons. The heating surfaces were of porcelain and initial decomposition of ethane was observed at 550° C. under 450-550 mm. pressure. Acetylene was not formed in any quantity and was believed not to play an important part in the reaction.

Frey and Smith[37] noted that in the presence of silica at 575° C. ethane decomposed into ethylene and hydrogen exclusively, the reaction being of the first order over a considerable pressure range. Pease[38] studied the mechanism of the decomposition of ethane, propane and n- and iso-butanes at 625° and 650° C. at 1 atmosphere and concluded that the two main reactions were dehydrogenation and demethanation. The total rate of dissociation increased with the complexity of the molecule and the reactions were probably homogeneous gas reactions of the first order. An explanation of the relative rates of dehydrogenation and demethanation was advanced by Pease in terms of the activation energies as a function of the size of the molecule and the nature of the linkage.

Pease and Durgan[39] contributed a study of the equilibrium $C_2H_6 \rightleftarrows C_2H_4 + H_2$. It is necessary to point out that, although ethane does resolve itself into hydrogen and ethylene at temperatures above 550° C. and the reverse reaction also takes place at low temperatures, this reaction, nevertheless, is not a true equilibrium because if ethane is heated for long periods at temperatures at which dehydrogenation takes place, the system will ultimately resolve itself into the well-known methane equilibrium. That this is true of most of the thermal reactions of hydrocarbons at their cracking temperatures was demonstrated theoretically and practically by Cantelo and others. In spite of this, however, chemists visualize a form of equilibrium called quasi- or instantaneous equilibrium, of a transitory nature. In other words, at any particular instant, a system is thermodynamically stable at a particular temperature although changes may take place at the next instant. The equilibrium between ethane, ethylene, and hydrogen above 550° to 600° C. is undoubtedly an example of instantaneous equilibrium and Pease and Durgan found that their results were to some extent obscured, especially at 700° C., by the formation of methane. The values obtained for the equilibrium constants,

$$K_{\text{atm.}} = \frac{[C_2H_4][H_2]}{[C_2H_6]} \times \frac{P}{100}$$

in which P is the partial pressure in atmospheres, are given in Table 11.

Hague and Wheeler[40] studied the decomposition of ethane at temperatures of 700° C. and over, in a vertical silica tube. At 700° C. the main reaction was found to be $C_2H_6 \rightarrow C_2H_4 + H_2$, 90 per cent of the ethane decomposing in this manner. At temperatures above 700° C., secondary reactions become important. It is considered likely that ethylene undergoes condensation to butadiene, which was observed at 750°, 800° and 850° C., according to the equation:

$$2CH_2{=}CH_2 \longrightarrow CH_2{=}CHCH{=}CH_2 + H_2$$

The formation of liquid hydrocarbons (mostly of an aromatic nature) was first noticed at 750° C., the yield increasing with rising temperature to a maximum at 900° C., when it corresponds with 21.9 per cent of the ethane used. The largest amount of distillate boiling between 80° and 90° C. was obtained at 850° C. and represented 11.2 per cent of the weight of ethane used. At 750° C. and 800° C. the liquid consisted largely of unsaturated hydrocarbons but, at 850° C. and above, the distillate was almost pure benzene, the residual oil consisting chiefly of naphthalene and anthracene.

By the pyrolysis of ethane in silica reaction tubes at 850° C. and with a period of contact of 0.05-0.10 minute, Frey and Hepp[41] obtained 10.5 per cent of volatile oils, mainly aromatic, calculated on the weight of ethane passed, while the gaseous products of pyrolysis contained 30.0 per cent by volume of unsaturated gases.

A careful study of the velocity of thermal dissociation of ethane into ethylene and hydrogen at temperatures of 600°-700° C. in copper reaction tubes was reported by Marek and McCluer.[42] Pure ethane was quickly preheated to reaction temperature and passed through a copper reactor at carefully controlled temperatures with short times of contact. The extent of pyrolysis in the reactor was determined by the difference in composition of the preheater and reaction coil samples. Under the conditions studied, namely at temperatures below 700° C. with short times of contact, ethane was found to decompose predominantly to ethylene and hydrogen; secondary reactions were negligible. The velocity constant of the decomposition of ethane, calculated from the general equation for unimolecular homogeneous gas reactions, was found to be satisfactorily represented by the following equation (temperature expressed as T° Absolute):

$$\log K_{C_2H_6} = 15.12 - \frac{15{,}970}{T}$$

The influence of temperature on the hydrogenation of ethylene to ethane[42a] could be represented by the equation,

$$\log K' = 8.79 - \frac{9140}{T}$$

which indicates that in the temperature range 600° to 700° C. the rate is approximately doubled for an increase of temperature of 25° C.

From the foregoing it can be concluded that ethane undergoes decomposition at temperatures up to 700° C. primarily into ethylene and hydrogen. At higher temperatures secondary reactions intervene with the production of methane, hydrogen, aromatic hydrocarbons, and butadiene, the ethylene yield rapidly diminishing with rise in temperature. However, in the presence of materials which promote decomposition of hydrocarbons into carbon and hydrogen, ethane undergoes almost complete decomposition even at temperatures below 700° C. into carbon and hydrogen. Complete decomposition of ethane into its elements has been found to occur in the presence of refractory material, pumice and iron at 725° C.,[43] of magnesium powder at red heat,[44] and of aluminum at its melting point,[45] and Sabatier and Senderens [46] noted the slow decomposition of ethane into its elements in contact with nickel at 325° C. A study of the thermal dehydrogenation of ethane in the presence of pumice impregnated with nickel and copper was made by Matignon, Kling, and Florentin,[47] who found that the formation of ethylene is favored by short times of contact with the catalyst and temperatures not above 600° C. In the presence of the nickel catalyst at 600° C., the composition of the cracked gas was: ethylene, 14.2 per cent; hydrogen, 22.0 per cent; ethane, 51.0 per cent; and methane, 12.8 per cent with a contact time of 42 seconds. With a longer time of contact (6.6 minutes) the composition of the cracked gas was: ethylene, 12.7 per cent; hydrogen, 40.7 per cent; ethane, 0 per cent; and methane, 49.9 per cent.

[41] *Ind. Eng. Chem.*, 1932, **24**, 282.

[42] *Ind. Eng. Chem.*, 1931, **23**, 878.

[42a] The hydrogenation of ethylene in the presence of activated charcoal containing a small proportion of iron and a trace of copper at temperatures from −84° to 75° C. was studied by Schuster (*Z. physik. Chem.*, 1931, **14B**, 249; *Brit. Chem. Abs.* **A**, 1931, 1374).

Travers and Hockin [48] observed that when ethane or ethane-ethylene-hydrogen mixtures were heated to 600° C., three reactions took place:

(1) The reversible reaction $C_2H_6 \rightleftharpoons C_2H_4 + H_2$;
(2) The formation of benzene and methane from ethane; and
(3) The formation of benzene and methane from ethane and ethylene.

Reactions (2) and (3) are related and are dependent upon the hydrogen concentration. Reaction (2) is endothermic, but (3) is exothermic.

An explanation of the thermal decomposition of paraffin hydrocarbons from the standpoint of free radicals has been given by Rice and his co-workers.[49] The relative strengths of the C—C and C—H bonds appear to indicate that decomposition of hydrocarbons takes place principally through the rupture of the C—C bonds; any breaking of a C—H bond must be wholly negligible compared with that of a C—C bond. The free radicals thus produced [50] can react in one of two ways: (1) decompose to form another free radical and hydrogen; or (2) take a hydrogen atom from the surrounding hydrocarbon molecule, since the probability that two free radicals will collide with each other is relatively small. The decomposition of the hydrocarbons can then take place according to chain reactions [51] in which the free hydrogen atoms or free radicals combine with the hydrogen atoms of the surrounding hydrocarbon molecules.

[50] Rice and Dooley (*J.A.C.S.*, 1933, **55**, 4245) showed the presence of free radicals when ethane is heated in the range 850°-950° C. The preparation of free methyl and ethyl radicals (from lead alkyls) has been studied by Paneth and Hofeditz (*Ber.*, 1929, **62**, 1335; *Chem. Abs.*, 1929, **23**, 5159); Paneth and Lautsch (*Ber.*, 1931, **64**, 2702, 2708; *Chem. Abs.*, 1932, **26**. 1232); and Simons and Dull (*J.A.C.S.*, 1933, **55**, 2696). Reactions of free ethyl radicals from the thermal decomposition of tetraethyl lead have been studied by Meinert (*J.A.C.S.*, 1933, **55**, 979).

[51] For a discussion of chain reactions see Rideal and Taylor, "Catalysis in Theory and Practice," Macmillan and Co., London, 1926, 37. Griffith and McKeown, "Photo-Processes in Gaseous and Liquid Systems," Longmans, Green and Co., New York, 1929, 544, 586, 640; Clusius, "Kettenreaktionen," Gebrüder Borntraeger, Berlin, 1932; *Fortschr. Chem. Physik physik. Chem. Ser.* **B**, 1932, **21**, 1-73; *Chem. Abs.*, 1933, **27**, 461.

For example, in the decomposition of ethane, the primary reaction (P_1) may be represented to be the formation of two free methyl radicals:

$$(P_1)\ CH_3CH_3 \longrightarrow 2CH_3{-}$$

These can then react, in secondary reactions (S_1 and S_2), to form ethyl radicals, methane, and ethylene:

$$(S_1)\ CH_3CH_3 + CH_3{-} \longrightarrow CH_4 + CH_3CH_2{-}$$
$$(S_2)\ CH_3CH_2{-} \longrightarrow CH_2{=}CH_2 + H$$

Thus, the chain reaction (A_1) is:

$$(A_1)\ CH_3CH_3 + H \longrightarrow H_2 + CH_3CH_2{-} \longrightarrow H_2 + CH_2{=}CH_2 + H$$

This decomposition of ethane is particularly simple because only one kind of chain cycle and one carrier, namely the hydrogen atom, is involved.

With higher hydrocarbons, however, the reaction becomes more complicated because of the possibility of hydrogen atoms other than those at the end of the hydrocarbon molecule taking part. With propane, for instance, the primary reaction (P_1) would be:

$$(P_1)\ CH_3CH_2CH_3 \longrightarrow CH_3CH_2{-} + CH_3{-}$$

The secondary reactions then depend upon whether the carrier groups (H or CH_3—) react with the primary (as in S_2) or secondary (as in S_3) hydrogen atom of propane:

$$(S_1)\ CH_3CH_2{-} \longrightarrow CH_2{=}CH_2 + H$$
$$(S_2)\ CH_3CH_2{-} + CH_3CH_2CH_3 \longrightarrow C_2H_6 + CH_3CH_2CH_2{-}$$
$$\longrightarrow C_2H_6 + CH_2{=}CH_2 + CH_3{-}$$
$$(S_3)\ CH_3CH_2{-} + CH_3CH_2CH_3 \longrightarrow C_2H_6 + CH_3CH(CH_3){-}$$
$$\longrightarrow C_2H_6 + CH_3CH{=}CH_2 + H$$

The chain reactions (A_1 and A_2) are, therefore:

$$(A_1)\ CH_3CH_2CH_3 + R \longrightarrow RH + CH_3CH_2CH_2{-}$$
$$\longrightarrow RH + CH_2{=}CH_2 + CH_3{-}$$
$$(A_2)\ CH_3CH_2CH_3 + R \longrightarrow RH + CH_3CH(CH_3){-}$$
$$\longrightarrow RH + CH_3CH{=}CH_2 + H$$

in which the carriers (R) are CH_3— or H.

Rice, therefore, concludes that the composition of the products of the decomposition is determined almost exclusively by the chain cycle and is practically independent of the primary decomposition of the hydrocarbon. Later, Rice[52] modified these considerations, assuming that methyl and ethyl groups are the only stable radicals and that a larger radical apparently decomposes to yield one or more molecules of an olefin, and either a methyl group, an ethyl group or atomic hydrogen. The relative probability of reactions of primary, secondary and tertiary hydrogen atoms are assumed to be 1 : 2 : 10, respectively.

Schmidt and Grosskinsky[53] state that, in the pyrolysis of many normal and cyclo-paraffins, hydrogen splits out at more than one point and the resulting double linkage determines the position at which breaking of the chain subsequently occurs. The adjacent single linkage is thus strengthened while the one beyond is weakened. This alteration, they believe, continues with diminishing intensity throughout the chain. Norris[54] states that it is possible to break the C—C linkages in paraffin hydrocarbons successively by regulating the temperature and thus determine from the products of the pyrolysis the order in which the bonds yield to this influence.

PROPANE

The thermal decompositions of propane and butane have not been studied as extensively as that of methane. From a study of the pyrolysis of the propane-butane fraction of natural gas, Zanetti[55] found that the percentage of total unsaturated hydrocarbons in the resulting gas increased to a maximum at 750° C. and then decreased, this latter process being coincident with the formation of aromatic hydrocarbons and also of free hydrogen.

Pease[56] concluded that the initial decomposition of propane was unimolecular, the two main reactions being dehydrogenation and demethanation. Frey and Smith[57] found that at 575° C. in the presence of silica, no carbon was formed and the reaction was unaffected by an increase in the surface area of the silica. Under these conditions, the decomposition of propane could be represented by the three equations:

$$(1)\ C_3H_8 \longrightarrow C_2H_4 + CH_4$$
$$(2)\ C_3H_8 \longrightarrow C_3H_6 + H_2$$
$$(3)\ 2C_3H_8 \longrightarrow C_3H_6 + C_2H_6 + CH_4$$

Of these, reactions (1) and (2) had fairly rapid velocities of the same order of magnitude, while (3) was much slower. Decomposition of propane in the presence of a nickel catalyst at 200°, 350°, and 405° C. led to the following changes:

$$(1)\ C_3H_8 \longrightarrow 2CH_4 + C$$
$$(2)\ C_3H_8 \longrightarrow C_3H_6 + H_2 \longrightarrow CH_4 + 2H_2 + 2C$$

of which (1) takes place at all temperatures and (2) becomes important only at higher temperatures.

Hague and Wheeler,[58] as a result of their very comprehensive work, came to the conclusion that the propane molecule undergoes decomposition in two ways, namely:

$$(1)\ CH_3CH_2CH_3 \longrightarrow CH_4 + CH_2{=}CH_2$$
$$(2)\ CH_3CH_2CH_3 \longrightarrow H_2 + CH_3CH{=}CH_2$$

At 700° C. in the presence of silica, reaction (1) proceeds to the extent of about 61 per cent, while reaction (2) proceeds to the extent of between 35 per cent and 39 per cent. At temperatures above 700° C. secondary changes largely occur, resulting in the decomposition of olefins to ethylene with the formation of butadiene and aromatics from the latter. The production of condensable liquid, which begins at about 700° C. and is still important at 1000° C., reaches a maximum at 850° C. (corresponding to 23.09 per cent of the weight of the propane used). At this temperature the part of the product distilling below 170° C. also attains a maximum value of 11.20 per cent by weight. At temperatures below 800° C. the liquid products are largely unsaturated and butadiene is found in the products at 750° C. and above. The use of porcelain tubes gave results similar to those obtained with silica tubes.

A study of the pyrolysis of propane in quartz tubes with and without catalysts and with special attention to the formation of gaseous olefins, has been made by Boecheler.[59] Experiments in quartz tubes without catalysts at temperatures of 500°-1000° C. showed that the main products of reaction were propylene, ethylene, and hydrogen and that there was an optimum temperature for the production of each gaseous olefin. The maximum propylene yield (13.7 per cent of the exit gas) was obtained at 805° C. The yield was increased by dilution with nitrogen, but dilution of the propane with half its volume of water vapor exerted no influence on the decomposition. The primary reaction was evidently dehydrogenation since an increase in the rate of flow of propane was accompanied by a decrease in the production of hydrogen and ethylene. The use of catalysts such as copper gauze, nickel gauze, and a mixture of zinc and copper, did not influence the character of the products but lowered the temperature necessary for their formation. A catalyst of 78.5 molar per cent zinc and 21.5 molar per cent chromium markedly increased propylene formation so that more of this hydrocarbon was produced at 655° C. than without a catalyst at 730° C. at a rate of flow only one-fourth of that at the latter temperature. An 11 per cent yield of propylene, based on propane, was obtained at temperatures as low as 520° C. when the propane was diluted with 67 per cent of nitrogen.

According to Ebrey and Engelder,[60] pyrolysis of propane in silica tubes at 600°-830° C. yields varying amounts of hydrogen, methane, ethane, ethylene and propylene, the unsaturated hydrocarbons being at a maximum at 770° C. Catalysts containing nickel, cobalt, chromium, or iron were found to favor the production of carbon and hydrogen.

Measurements of the rate of pyrolysis of propane in the presence of such reaction surfaces as silica or copper have shown that the reaction is homogeneous and gives velocity constants in agreement with a first order reaction. Pease and Durgan[61] found that the first order constants fall rather rapidly as reaction proceeds, probably on account of secondary changes, and that dilution with nitrogen somewhat increases the velocity of pyrolysis. The temperature coefficient of reaction was found by these workers to be about 2.75 per 25° C. and the heat of activation 65,000 cal. per mole. A careful study of the rates of pyrolysis of propane in a copper reaction coil at temperatures of 587°-679° C. was carried out by Marek and McCluer,[62] who found that the constants were in agreement with those required for a homogeneous unimolecular process. The principal reactions occurring were found to be dehydrogenation and demethanation, the rates of the two reactions being approximately the same. From the experimental results, Marek and McCluer calculated the following relationship between the temperature (T° Abs.) and the unimolecular reaction coefficient, k,

$$\log k = 13.44 - \frac{13{,}500}{T}$$

Schneider and Frolich[63] carried out work of fundamental importance on the pyrolysis of propane and other gases, the object of their experiments being the elucidation of the mechanism of the primary reactions occurring prior to aromatization. The method adopted in studying the reaction mechanism was to vary the degree of cracking within the range where accurate analysis of the products was possible and then to plot the results in such a manner that extrapolation to zero per cent cracking distinguishes the primary cracking products from the secondary ones. Obviously, those compounds whose production curves intersect the zero ordinate at a positive value are primary products and the others are secondary. The results obtained by subjecting propane to pyrolysis in silica reaction tubes at various temperatures and under atmospheric pressure are shown in the accompany-

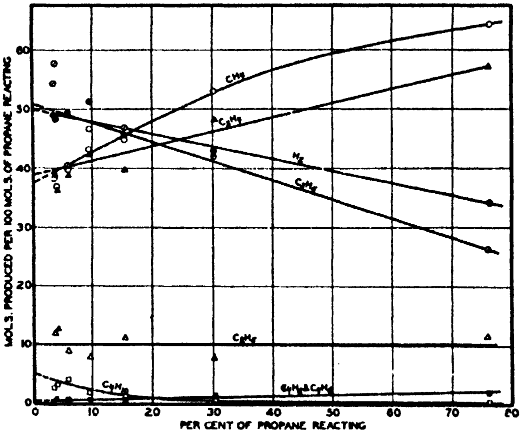
FIG. 3.—Pyrolysis of Propane at 725° C. and 1 Atmosphere. (Schneider and Frolich.)

ing graphs (Figs. 2, 3, and 4). It will be seen that at 725° C. and 1 atmosphere pressure, at zero per cent cracking propane decomposes to the extent of 48 per cent (molar) according to the equation $C_3H_8 \rightarrow C_2H_4 + CH_4$, while 42 per cent is converted into propylene and hydrogen according to the equation $C_3H_8 \rightarrow C_3H_6 + H_2$. Ethane also appears to be a primary product though the reaction responsible for its initial formation is not quite clear. The curves for butadiene and the higher hydrocarbons (Fig. 3) both pass through the origin, showing that these are definitely secondary reaction products. The results of cracking experiments at 650° C. and 1 atmosphere pressure (Fig. 4) show that about 50 per cent of the propane undergoes dehydrogenation to propylene and somewhat less than 40 per cent is demethanated to yield ethylene and methane. Both ethane and butane appear to be primary reaction products which may be formed according to the equation $2C_3H_8 \rightarrow C_2H_6 + C_4H_{10}$.



Courtesy Industrial and Engineering Chemistry.

FIG. 4.—Pyrolysis of Propane at 650° C. and 1 Atmosphere. (Schneider and Frolich.)

Of the two main primary reactions occurring in the pyrolysis of propane, the dehydrogenation predominates somewhat at the lower temperature studied (650° C.) but at a higher temperature (725° C.) there is a greater tendency for the C—C bond to be disrupted with the formation of ethylene and methane. The homogeneous and apparently unimolecular character of the cracking reactions was confirmed by the work of Schneider and Frolich.

Rice[64] has represented the decomposition of propane as follows: The principal reaction (P_1) produces both free ethyl and methyl radicals:

$$(P_1)\ CH_3CH_2CH_3 \longrightarrow CH_3CH_2— + CH_3—$$

The secondary reactions (S_1, S_2 and S_3) are as follows:

$$(S_1)\ CH_3CH_2— \longrightarrow CH_2{=}CH_2 + H$$

$$(S_2)\ CH_3CH_2— + CH_3CH_2CH_3 \longrightarrow C_2H_6 + CH_3CH_2CH_2— \longrightarrow C_2H_6 + CH_2{=}CH_2 + CH_3—$$

$$(S_3)\ CH_3CH_2— + CH_3CH_2CH_3 \longrightarrow C_2H_6 + CH_3CH(CH_3)— \longrightarrow C_2H_6 + CH_3CH{=}CH_2 + H$$

---

[64] *J.A.C.S.*, 1931, 53, 1965.

The two chain reactions (A_1 and A_2), the relative extents of which depend upon whether the carrier group (R is CH_3— or H in this reaction) reacts with the primary (as in S_2) or the secondary (as in S_3) hydrogen atom of propane, are as follows:

$$(A_1)\ CH_3CH_2CH_3 + R \longrightarrow RH + CH_3CH_2CH_2{-} \longrightarrow RH + CH_2{=}CH_2 + CH_3{-}$$

$$(A_2)\ CH_3CH_2CH_3 + R \longrightarrow RH + CH_3CH(CH_3){-} \longrightarrow RH + CH_3CH{=}CH_2 + H$$

Rice has found good agreement between the experimental results of Pease and Durgan[65] and the values predicted by his theory.

In the presence of a copper-pumice catalyst[66] at 500° C., dehydrogenation to propylene is the predominant reaction and only small amounts of ethylene and methane are produced. The formation of propylene is favored by short time of contact with this catalyst, prolonged contact increasing yields of methane and ethylene.

BUTANES

Pease,[67] conducting a preliminary study of the decomposition of n-butane, concluded that demethanation and dehydrogenation were the two main reactions involved. Hague and Wheeler[68] investigated the thermal decomposition of n-butane in the presence of silica and concluded that the primary changes which take place at low temperatures (650° to 700° C.) can be represented satisfactorily by the equations:

$$(1)\ CH_3CH_2CH_2CH_3 \longrightarrow CH_3CH_3 + CH_2{=}CH_2$$

$$(2)\ CH_3CH_2CH_2CH_3 \longrightarrow CH_4 + CH_3CH{=}CH_2$$

$$(3)\ CH_3CH_2CH_2CH_3 \longrightarrow H_2 + CH_3CH_2CH{=}CH_2$$

From a careful examination of the products of the reaction it was concluded that at 650° C. in the presence of silica or porcelain about 43 per cent of butane decomposed according to reaction (1), while reactions (2) and (3) accounted for 36 per cent and 21 per cent, respectively. Liquid products of n-butane appear definitely at 700° C. and are still in evidence at 950° C. Between these two temperatures the yields attain maxima, the total oil yield at 850° C. and the "distillate up to 170° C." yield at 800° C., with values of 24.61 per cent and 12.9 per cent by weight of the butane used, respectively. At temperatures above 750° C. the distillate from the liquids obtained was almost all benzene.

Hurd and Spence[69] conducted a study of the pyrolysis of both n-butane and isobutane by passing these gases through pyrex glass tubes at 600° and 700° C. With n-butane the two main concurrent reactions at 600° C. are:

$$(1)\ CH_3CH_2CH_2CH_3 \longrightarrow CH_4 + CH_3CH{=}CH_2$$

$$(2)\ CH_3CH_2CH_2CH_3 \longrightarrow CH_3CH_3 + CH_2{=}CH_2$$

The first of these reactions is slightly favored. Two major reactions also occur in the pyrolysis of isobutane at 600° C., the formation of propylene and methane, according to the equations:

---

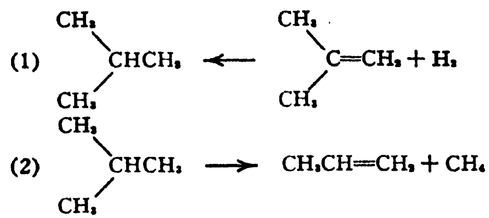
[65] *Loc. cit.*

[66] Matignon, Kling and Florentin, *Compt. rend.*, 1932, **194**, 1040.

[67] *Fuel*, 1929, **8**, 576.

[68] *Loc. cit.*

[69] *J.A.C.S.*, 1929, **51**, 3353.



These reactions are still the major ones of n-butane and isobutane at 700° C., but secondary reactions already begin to occur at that temperature.

Neuhaus and Marek[70] have made a special study of the primary reaction products of the pyrolysis of n-butane at 600° C. and 650° C. in the presence of silica reaction surfaces. Their method was the same as that employed by Schneider and Frolich, i.e., the experimental data were plotted graphically as moles of each product formed per 100 moles of n-butane reacting against the percentage of n-butane reacting. On extrapolation to zero per cent cracked, a clear distinction between primary and secondary reaction products was obtained, the curves for secondary products passing definitely through the origin. The experimental results are shown graphically in Figures 5 and 6, from which the distribution of primary products per 100 moles of n-butane reacting was calculated as shown in Table 12.

FIG. 6.—Cracking of n-Butane at 650° C.
(Neuhaus and Marek.)

The primary reactions, in the order of their importance, are therefore:

(1) $CH_3CH_2CH_2CH_3 \longrightarrow CH_4 + CH_3CH{=}CH_2$ (about 48 per cent);
(2) $CH_3CH_2CH_2CH_3 \longrightarrow C_2H_6 + CH_2{=}CH_2$ (about 35 to 38 per cent);
(3) $CH_3CH_2CH_2CH_3 \longrightarrow CH_3CH{=}CHCH_3 + H_2$ (about 12 to 16 per cent).[70a]

No butadiene or aromatic hydrocarbons were formed under the conditions studied and the reaction was shown to obey the equation for a first-order homogeneous gas reaction.

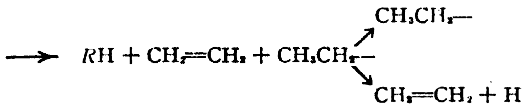
Rice [71] has represented the reactions occurring in the decomposition of n-butane as follows:

The principal reactions (P_1 and P_2) yield either free methyl, ethyl or propyl radicals:

(P_1) $CH_3CH_2CH_2CH_3 \longrightarrow CH_3{-} + CH_3CH_2CH_2{-}$
(P_2) $CH_3CH_2CH_2CH_3 \longrightarrow 2CH_3CH_2{-}$

The chain reactions (A_1 and A_2), in which the carriers (R) are $CH_3{-}$, $CH_3CH_2{-}$ or H, can then be derived and are:

(A_1) $CH_3CH_2CH_2CH_3 + R \longrightarrow RH + CH_3CH_2CH_2CH_2{-}$



$$\longrightarrow RH + CH_2{=}CH_2 + CH_3CH_2{-} \begin{cases} \nearrow CH_3CH_2{-} \\ \searrow CH_2{=}CH_2 + H \end{cases}$$

(A_2) $CH_3CH_2CH_2CH_3 + R \longrightarrow RH + CH_3CH(CH_2CH_3){-}$
$\longrightarrow RH + CH_3CH{=}CH_2 + CH_3{-}$

Theoretical results predicted from these reactions are in good agreement with those obtained by Pease and Durgan.[72]

[70a] The butylenes formed appeared to consist of about 20 per cent 1-butene, the remainder being 2-butene.
[71] *J.A.C.S.*, 1931, 53, 1967.
[72] *J.A.C.S.*, 1930, 52, 1266.

If the ratio of reaction (2) to reaction (1) of Neuhaus and Marek (see above) is compared with the values predicted by Rice, the following agreement is calculated:

$$\text{Ratio}\left\{\frac{\text{Reaction (2)}\quad C_2H_6 + CH_2{=}CH_2}{\text{Reaction (1)}\quad CH_4 + CH_3CH{=}CH_2}\right.$$

Temp. ° C.	Predicted by Rice	Found by Neuhaus and Marek
600° C.	0.75	0.71
650° C.	0.79	0.79

Fig. 7.—Products Formed in the Thermal Decomposition of Isobutane at 600° C. (Marek and Neuhaus.)

The thermal decomposition of isobutane at 600° and 650° C. in silica tubes was later studied by Marek and Neuhaus.[73] The results are represented graphically in Figures 7 and 8, and the distribution of primary reaction products per 100 moles of isobutane reacting is shown in Table 13.

Table 13.—*Isobutane.*

	At 600° C.	At 650° C.

Isobutylene	63.0	63.0
Methane	35.0	36.0
Propylene	34.0	36.0
Ethane	2.5	1.5

The primary reactions in order of their importance are:

(1) $(CH_3)_3CH \longrightarrow (CH_3)_2C{=}CH_2 + H_2$ (63 per cent)

(2) $(CH_3)_3CH \longrightarrow CH_3CH{=}CH_2 + CH_4$ (about 34 to 35 per cent).

---

[73] *Ind. Eng. Chem.*, 1933, 25, 516.

The agreement of these experimental results with the predictions of Rice[74] are not as good as in the pyrolysis of n-butane. The ratios of the number of moles of isobutane reacting to form methane and propylene to the number of moles reacting to form hydrogen and isobutylene are as follows:

$$\text{Ratio}\left\{\frac{\text{Reaction (2)}\quad CH_4 + C_3H_6}{\text{Reaction (1)}\quad H_2 + C_4H_8}\right.$$

Temp. ° C.	Predicted by Rice	Determined

FIG. 8.—Products Formed in the Thermal Decomposition of Isobutane at 650° C. (Marek and Neuhaus.)

A detailed examination of the volatile oils obtained from the pyrolysis of a mixture of 89 per cent n-butane and 11 per cent isobutane at 850° C. in silica reaction tubes has been made by Frey and Hepp,[75] who found the oil to contain propylene, butenes (chiefly isobutene), 1,3-butadiene, pentenes, cyclopentadiene, hexadienes, methylcyclopentadiene, benzene, toluene, xylenes and styrene.

From a study of the kinetics of the pyrolysis of the butanes, Pease and Durgan[76] concluded that the processes involved are fundamentally first order homogeneous gas reactions, though the velocity coefficients fall rapidly as pyrolysis proceeds. At low pressures the constants are distinctly less than at 1 atmosphere. Dilution with nitrogen increases the velocity constants to some extent.

In the course of a study of the thermal dehydrogenation of gaseous paraffin hydrocarbons in the presence of copper and nickel on pumice, Matignon, Kling, and Florentin[77] found that at 500° C. with a copper catalyst, the predominant reaction is

$$C_4H_{10} \longrightarrow C_3H_6 + CH_4 - 17\text{ Cals.},$$

[74] *J.A.C.S.*, 1931, 53, 1959.

[75] *Ind. Eng. Chem.*, 1932, 24, 282.

[76] *J.A.C.S.*, 1930, 52, 1262.

[77] *Compt. rend.*, 1932, 194, 1040.

while about 20 per cent decomposition occurs according to the equation

$$C_4H_{10} \longrightarrow C_4H_8 + H_2 - 32.7 \text{ Cals.}$$

On the other hand, the reaction

$$C_4H_{10} \longrightarrow C_2H_6 + C_2H_4 - 16.4 \text{ Cals.}$$

does not occur below 520° C. (using a copper catalyst) but is markedly favored by rise in temperature, becoming predominant at 600° C.

PENTANES

Norton and Andrews[78] were among the first to investigate the thermal decomposition of pentane and concluded that, at a "red heat," ethylene, propylene, butadiene and paraffin hydrocarbons were produced but no benzene. A more precise investigation of the pyrolysis of n-pentane and isopentane at 600° C. was made by Calingaert.[79] The unsaturated hydrocarbons in the exit gas were examined by bromination methods, followed by fractionation of the resulting olefin bromides. It was considered that the n-pentane molecule was disrupted at the central carbon atom, giving ethyl and propyl groups, one of which was saturated at the expense of the other. Of the n-pentane decomposed, Calingaert concluded that about 55 per cent follows the reaction:

$$(1)\ CH_3CH_2CH_2CH_2CH_3 \longrightarrow CH_3CH_3 + CH_3CH{=}CH_2$$

25 per cent decomposes according to the reaction:

$$(2)\ CH_3CH_2CH_2CH_2CH_3 \longrightarrow CH_3CH_2CH_3 + CH_2{=}CH_2$$

and most of the remainder decomposes to methane and butylene:

$$(3)\ CH_3CH_2CH_2CH_2CH_3 \longrightarrow CH_4 + CH_3CH_2CH{=}CH_2$$

Calingaert found that at 600° C. the isopentane molecule was disrupted on one or the other side of the tertiary carbon atom giving: in the first case, a methyl and isobutyl group (which, by saturation of the lighter group, yields methane and 1- or 2-butene) and, in the second case, an ethyl and an isopropyl group, the ethyl group always becoming saturated since no ethylene was found. Besides these two reactions a small amount of amylene was formed. Thus isopentane yields methane and the butylenes by one reaction and ethane and propylene by a second.

Hague and Wheeler[80] concluded from their work that the important changes in the pyrolysis of n-pentane up to 700° C. appear to be demethanation, dehydrogenation and "de-ethylenation" (a word coined to express the elimination of ethylene). The extent to which the olefins are eliminated, and also their character, was rather uncertain. Contrary to the experience of Calingaert, the gas mixture obtained at 600° C. contained methane, ethylene, and higher olefins in proportions decreasing in that order. At higher temperatures aromatic hydrocarbons were formed, the best yields being at 850° C., corresponding to a total yield of oil of 26.80 per cent by weight of the pentane, of which 11.87 per cent distilled over between 80° and 90° C.

Norris and Thomson[81] have made careful measurements of the effect of temperature upon the rate of pyrolysis of n- and isopentanes in the region of incipient dissociation. The hydrocarbons were heated in the vapor phase for about one hour at a definite temperature in a glass apparatus in which the expansion occurring under atmospheric pressure could be measured. At temperatures below those of decomposition, no expansion was evident after the attainment of thermal equilibrium. As the temperature was raised, step by step, a temperature was reached at which a definite expansion due to pyrolysis continued throughout the hour. The results obtained with n-pentane are shown in Figure 9, from which it will be seen that the initial temperature of pyrolysis is about 391° C. Since one definite break in the curve occurs at 423° C. and another at 451° C., Norris and Thomson believed it likely that one type of decomposition takes place in the range 389°-423° C., another between 423° and 451° C., and the greatly increased rate above 451° C. indicates more profound cracking of still a third kind. Experiments (not reported) were stated to indicate that at 10° above the initial cracking temperature, as observed by the above method, a simple decomposition takes place as the result of the fission of a C—C bond. In the case of isopentane the initial cracking temperature was found to be 383° C. and two breaks, at 423° and 450° C., were revealed on the cracking curve.

FIG. 9.—n-Pentane Cracking Rate Curve. 1 Scale Division = 0.09 cc. at 40° C. (Norris and Thomson.)

HEXANE

Norton and Andrews[82] found that no gas was evolved from hexane at 550° C., but at 600° C. decomposition had begun and at 700° C. a liquid, thought to contain pentene and hexene, was obtained. At 700° C. propylene and butylenes were noticed in the gas but no ethylene. Benzene was formed at a bright red heat. Haber[83] reported that at temperatures between 600° and 800° C., n-hexane decomposes with the elimination of methane according to the equation:

$$CH_3CH_2CH_2CH_2CH_2CH_3 \longrightarrow CH_4 + CH_3CH_2CH_2CH{=}CH_2$$

This dissociation he regarded as typical of the paraffin hydrocarbons.

Ipatiev and Dowgelewitsch[84] obtained ethylene, propylene, possibly isobutylene, and paraffin hydrocarbons by decomposing hexane in an iron tube at 650°-700° C. At 710° C. the gas contained 50 per cent unsaturated and 41.6 per cent saturated hydrocarbons together with 8.4 per cent hydrogen, and a 75 per cent yield of liquids boiling at 37° to 72° C. was also recovered.

[83] *Ber.*, 1896, 24, 2691.
[84] *Ber.*, 1911, 44, 298.

Hague and Wheeler[85] found that the thermal decomposition of n-hexane was appreciable in the presence of silica at 600° C., but a complete mechanism of the decomposition could not be advanced owing to difficulties in the estimation of the amylenes and butylenes. At temperatures up to 700° C. the important constituents of the gaseous products were methane, ethylene, higher olefins, and hydrogen in that order. From the high proportion of methane obtained, the principal reaction appeared to be:

$$CH_3CH_2CH_2CH_2CH_2CH_3 \longrightarrow CH_4 + CH_3CH_2CH_2CH{=}CH_2$$

in agreement with the results of Haber. The general results were similar to those obtained from n-pentane, the important changes probably being demethanation and de-ethylenation, although dehydrogenation was of far less importance. The production of aromatic liquids was at its maximum between 800° and 850° C. The total yield of oil at 850° C. was 33.8 per cent of the weight of hexane used and, of this, 19.0 per cent represented light fraction.

HIGHER PARAFFIN HYDROCARBONS

Very little work has been carried out apparently on the thermal decomposition of paraffin hydrocarbons possessing more than 6 carbon atoms, a fact which can be ascribed partly to the difficulty of preparing such hydrocarbons in the pure state and partly to difficulties in the analysis of the products of reaction.

Vohl[86] advanced the view that the higher paraffins were decomposed initially into a paraffin of high molecular weight and an olefin of low molecular weight but this theory is now regarded as untenable in the light of more recent work.

The first work of importance was that of Thorpe and Young,[87] who studied the effect of distilling a paraffin wax of melting point 46° C. (containing C, 85.14 per cent; H, 14.81 per cent) under a pressure of about 2 atmospheres. Besides a comparatively small amount of gas the products were liquids, boiling for the most part between 100° and 300° C., while only 7 per cent boiled between 18° and 100° C. It was found that in the lower fractions the liquid consisted of approximately equal proportions of paraffin and olefin hydrocarbons and that the higher fractions had a somewhat lower paraffin content. Thorpe and Young concluded that there was a decided tendency for the high molecular weight paraffin to undergo a symmetrical scission of its molecule with the production of equal parts of lower paraffin and olefin. Assuming, for the sake of simplicity, that this may occur as low down the series as butane, it was concluded that the primary decomposition was:

$$CH_3CH_2{-}CH_2CH_3 \longrightarrow CH_3CH_3 + CH_2{=}CH_2$$

Among the products identified were amylene, pentane, hexene, hexane, heptene, heptane, octene, octane, nonene, nonane, undecene, undecane, and possibly caprylidene but no trace of benzene was found.

Tocher[88] studied the thermal decomposition of octane, decane and several paraffin distillates from the point of view of determining the value of these materials for oil-gas manufacture. He concluded that at low temperatures octane and decane are decomposed into ethylene and higher olefins, methane and hydrogen, while at higher temperatures no higher olefins are formed, the gaseous products being simply ethylene, methane, and hydrogen.

---

[85] *Fuel*, 1929, 8, 583; *J.C.S.*, 1929, 378.
[86] *Polytechn. J.*, 1865, 177, 58.
[87] *Proc. Roy. Soc.*, 1871, 19, 370; 1872, 20, 488; *Ann.*, 1873, 165, 1.
[88] *J.S.C.I.*, 1894, 13, 231.

It is doubtful whether the primary products of decomposition were actually observed by Tocher. Haber[89] in 1896, in his work on the pyrolysis of hexane already mentioned, reached several other important conclusions which must now be considered. The decomposition of a paraffin molecule was believed to give rise primarily to a paraffin and an olefin. From hexane, pentene and methane were formed, but secondary reactions intervened, obscuring the result, and there may have been a condensation of the unsaturated residues to form higher molecular weight substances. Haber concluded that there is a lack of equilibrium in processes of this type, this being in agreement with the later conclusion of Cantelo[89a] that the thermal decomposition of all higher hydrocarbons at temperatures above about 500° C. ultimately resolves itself into the equilibrium

$$CH_4 \rightleftharpoons C + 2H_2$$

Worstall and Burwell[90] examined the decomposition of an impure heptane-octane mixture in a Pintsch-gas retort heated externally to about 900° C. With the possible exception of some ethane, methane was the only paraffin constituent of the gas, while the main products in the compression liquid and tar were unsaturated and aromatic hydrocarbons. Comment was made by these workers on the remarkable qualitative similarity of the products obtained by decomposing various types of raw hydrocarbon materials under these conditions.

Work of importance on this subject was contributed by Engler and Spanier,[91] who passed fractions of an American kerosene corresponding to paraffin hydrocarbons of 9 to 16 carbon atoms through a glass tube 80 cm. long, heated to temperatures of 460°-480° C., and found the gas obtained consisted chiefly of gaseous paraffins with only relatively small amounts of hydrogen. Some of the results of these investigators are given in Table 14.

	470–480	10	30	70	1.9	97.5	0.6
	480–490	10	30	100	1.7	97.5	0.8

When, in another series of experiments, heptane was heated to 480° to 490° C., 500° to 510° C., and 520° to 530° C., the amounts of hydrogen in the reaction gas were 3.6 per cent, 3.9 per cent and 10.2 per cent, respectively.

This work of Engler and Spanier shows very clearly that the initial course of the decomposition of the higher paraffins is such that the lower paraffins are first eliminated. The production of appreciable quantities of hydrogen does not take place until higher temperatures are attained and presumably as a result of secondary changes.

Egloff and Moore [92] examined the thermal decomposition of the following fractions of a Pennsylvania paraffin-base petroleum: (1) up to 150° C., (2) 150° to 200° C., (3) 200° to 250° C., and (4) above 250° C., the last fraction being separated into two cuts by distillation *in vacuo*. Each of these fractions was passed at the same rate through a tube-furnace at 700° C. Some of the results are given in Table 16.

TABLE 16.—*Decomposition of Pennsylvanian Petroleum Fractions at 700° C.*

B.P. Fraction ° C.	Original Oil Recovered	Original Oil Converted to Gas and Carbon	Liters of Gas Formed per Liter of Oil
	Per Cent	Per Cent	
Up to 150	2.3	97.7	710.2
150–200	29.3	70.7	560.7
200–250	66.7	33.3	420.4
150–200/*vacuo*	25.0	75.0	476.7
200–250/*vacuo*	20.0	80.0	514.4

Egloff and Moore considered that these results demonstrated that the hydrocarbons boiling between 200° and 250° C. and of the empirical formula $C_{12}H_{26}$ to $C_{16}H_{32}$ were more stable thermally than either the higher-boiling or lower-boiling fractions of the same petroleum. This conclusion, however, needs more confirmation since there may be another explanation of the above results. Furthermore, it is doubtful whether such conclusions could be validly applied generally to the paraffin hydrocarbons because the higher fractions of even a paraffin-base petroleum undoubtedly contain hydrocarbons of other series.

Gault and Hessel [93] examined the thermal decomposition of hexadecane at various temperatures and in furnaces of various lengths. It was found that in the gaseous products, the unsaturated hydrocarbons increased to a maximum at about 540° C. and then decreased regularly. The proportion of saturated hydrocarbons in the gas passed through a minimum at 615° C., while, as usual, the hydrogen content increased with rise in temperature. They believed that the following reactions took place:

---

[92] *Chem. Met. Eng.*, 1917, 16, 47.

[93] *Compt. rend.*, 1924, 179, 171; *Ann. chim.*, 1924, 2, 319; *Chem. Abs.*, 1925, 19, 966. See also Seyer, *J. Inst. Pet. Tech.*, 1933, 19, 779.

(a) Hexadecane distilled undecomposed at 390° C.

(b) Saturated and unsaturated gaseous and liquid hydrocarbons were obtained at 470° C., though no hydrogen was formed at this temperature. Reactions at this temperature were represented by:

$$(1)\ RCH_2CH_2CH_2R' \longrightarrow RCH{=}CH_2 + CH_3R'$$
$$(2)\ CH_3(CH_2)_{14}CH_3 \longrightarrow CH_3(CH_2)_{12}CH{=}CH_2 + CH_4$$
$$(3)\ CH_3(CH_2)_{14}CH_3 \longrightarrow CH_3(CH_2)_{12}CH_3 + C_2H_4$$

(c) At 540° C. another reaction occurs in which hydrogen is formed:

$$RCH_2CH_2CH_2R' \longrightarrow RCH{=}CH_2 + CH_2{=}CHR' + H_2$$

(d) At 685° C. not only hydrogen but also aromatic hydrocarbons were produced. The latter are apparently the result of the following transformations:

Olefins $\longrightarrow$ Cyclohexane $\longrightarrow$ Cyclohexene $\longrightarrow$ Cyclohexadiene $\longrightarrow$ Benzene

Some aromatics (benzene) may possibly have been formed by the polymerization of acetylene.

Waterman and his collaborators[94] have done much work on the decomposition of Rangoon paraffin wax both under ordinary and increased pressure. Special attention was given to the decomposition which occurs at relatively low temperatures (327°-385° C.) under normal pressure. Thus, when 90 grams of Rangoon paraffin wax were heated to 385° C. for several hours there was produced a gas containing 18.5 cc. of hydrogen, 62.3 cc. of methane, 253.3 cc. of methane homologues (n in $C_nH_{2n+2} = 2.94$) and 167.1 cc. of unsaturated hydrocarbons (n in $C_nH_{2n} = 2.68$). The production of hydrogen in this initial stage of the decomposition is worthy of note.

The primary decomposition reactions of 2,3-dimethylbutane and n-hexane, as well as those of n-butane, isobutane, n-pentane, isopentane and 2,2-dimethylpropane in a silica tube at 575° C. were studied by Frey and Hepp.[95] Scission of the carbon chain resulted in the formation of a molecule of paraffin and a molecule of the complementary olefin (i.e., the olefin which results from the splitting out of the paraffin) when the paraffin formed was methane. When a higher paraffin was produced, part of it appeared as the corresponding olefin and hydrogen. n-Pentane and n-hexane, however, did not give equal proportions of complementary products, their behavior being in accordance with a chain-reaction mechanism postulating the formation and subsequent decomposifion of free alkyl radicals. When olefins were produced by splitting of the side-chain, the ethylene linkage was in the inner position and not at the end of the chain. The normal paraffin yielded only 1-olefins. 2-Butene was found in both isomeric forms (trans- and cis-2-butenes).

SUMMARY OF THERMAL REACTIONS OF PARAFFIN HYDROCARBONS

The conclusions to be drawn from the preceding outline of the decomposition of the paraffins may be briefly summarized as follows:

(1) Methane is the most stable of the paraffins and is always an important product of the thermal decomposition of all other hydrocarbons. Both from a theoretical and practical point of view there is reason to believe that at temperatures above about 500° C. (except perhaps at very high temperature when acetylene appears to be stable) the decomposition of all hydrocarbons resolves itself into the methane equilibrium $CH_4 \rightleftarrows C + 2H_2$. It should be pointed out, however, that this is an ultimate condition which is attained only after considerable

---

[95] *Ind. Eng. Chem.*, 1933, 25, 441.

time in the absence of active catalysts, and is never approached in commercial cracking operations.

(2) The most striking feature of the thermal decomposition of the paraffin hydrocarbons up to hexane (and probably also throughout the series), is the similarity of their behavior at the higher temperatures. Below approximately 750° C. the primary decompositions are taking place and each hydrocarbon follows its own special course, but at higher temperatures similar products are obtained, namely ethylene (whose production attains a maximum at about 700°-750° C. except in the case of methane), butadiene, and aromatic hydrocarbons as well as hydrogen, methane and carbon.

(3) The work of Hague and Wheeler on the pyrolysis of the paraffins up to hexane showed that the primary decomposition of the paraffins results in a rupture of the chain at any position with the production of an olefin and the complementary lower paraffin, or, in the limit, of hydrogen. As the series is ascended, the tendency for hydrogen to be eliminated leaving an olefin with the same number of carbon atoms rapidly diminishes. Carbon is never produced in the primary stage of the reaction.

(4) As regards the stability of the higher paraffin hydrocarbons, too little work has been carried out for a generalization to be made. From the work of Egloff and Moore it appears that paraffins having 12 to 15 carbon atoms are more stable than their immediate homologues but this requires confirmation. It is certain, however, that the higher solid paraffins are much less stable, their decomposition occurring at much lower temperatures. Little is known, moreover, of the mode of decomposition of the higher paraffins. Burrell[96] has concluded that at comparatively low temperatures symmetrical splitting of the molecule takes place with the production of approximately equal amounts of paraffin and olefin of nearly equal molecular weight, while higher temperatures cause the splitting off of lower paraffins (methane and ethane, for example) with the formation of high molecular weight olefins. The work of Engler and Spanier is consistent with the view that decomposition takes place with the splitting off of the lower paraffins, the production of hydrogen being very small. It is true that Waterman and his co-workers noted the production of hydrogen from paraffin wax at 385° C., but much larger amounts of gaseous saturated hydrocarbons were simultaneously formed. It is probable also that molecular constitution greatly influences the course of thermal decomposition of the higher paraffins.

(5) Most of the foregoing conclusions are only valid when the thermal decomposition takes place in the presence of inactive materials such as silica, porcelain, or glass. Substances such as iron and nickel tend greatly to hasten the attainment of the ultimate state of equilibrium (as distinct from simultaneous, or quasi-equilibrium) which, in the case of hydrocarbons above 500° C., can be represented by $CH_4 \rightleftarrows C + 2H_2$. Certain catalysts, moreover, have a specific action in accelerating some types of reactions and not others. The action of aluminum chloride in splitting off gaseous paraffin molecules is noteworthy in this respect. (See Chapter 6). The time of heating and the area, as well as nature, of the heating surface are also factors which must be taken into consideration.

Thermodynamic Considerations. By using the Nernst Heat Theorem it is possible to calculate from thermal data alone the equilibrium constants of all possible (and also impossible) reactions at various temperatures. Given the necessary thermal data, one can calculate (1) which of several possible reactions leads to the most stable state of a system, (2) whether a conceivably possible reaction can actually occur, (3) the magnitude of the driving force tending to cause the reaction to proceed, and (4) the conditions of equilibrium in the system for the reaction under consideration.

---

[96] *Ind. Eng. Chem.*, 1928, 20, 602.

It is of importance to note, however, that the laws of thermodynamics tell us nothing whatever about the relative velocities with which reactions take place, the rate of chemical change depending on a number of factors, notably on the presence of catalytic materials. By the aid of thermodynamics, calculations of free energies of hydrocarbons and of equilibrium constants of cracking reactions have been made by a number of workers and conclusions drawn from them regarding the thermal decomposition of the paraffin hydrocarbons.

Francis,[97] from a calculation of free energies of hydrocarbons at various temperatures, arrives at the following conclusions in regard to the paraffins.

(1) At low temperatures, paraffins are more stable than olefins with the same number of carbon atoms, while at high temperatures the olefins are more stable.

(2) The direct production of higher hydrocarbons from lower ones, except with simultaneous formation of still lower ones in at least equivalent amount, is thermodynamically impossible.

(3) Dissociation of paraffins to hydrogen and olefins of the same number of carbon atoms can occur at higher temperatures but under these conditions (700° C.) more complete disruption of the molecule is favored.

(4) Of all the hydrocarbons, the paraffins are least stable at higher temperatures.

Sachanen and Tilicheyev[98] from a calculation of the equilibrium constants of various cracking reactions at 477° C. reached the conclusion that the tendency of paraffins to break at the middle of the chain (with production of lower paraffin and olefin of almost the same molecular weight) increases with increase in the molecular weight of the paraffin concerned. The other conclusions of Francis were substantiated.

When the above deductions from thermodynamic laws are compared with the results of experiment it will be found that, in the main, there is good agreement. It must be pointed out, however, that the deductions from thermodynamic equations may be nullified merely by taking advantage of the slowness of the decomposition of some compounds, as was done by Fischer and other investigators on the production of higher hydrocarbons from methane.

THERMAL DECOMPOSITION OF OLEFINS

Ethylene

Dalton and Henry[99] in 1808 observed that when electric sparks were passed for some time through ethylene, it was resolved into carbon and two volumes of hydrogen. Deiman, van Troostwyk, Bondt and Lauwerenburgh[100] reported that a red heat acted like electricity except that it converted a portion of the gas into marsh gas (methane) and an aromatic oil. They noticed that when metals were present these were converted into carbides. Sefström[101] used heated iron wire, and Marchand[102] employed porcelain fragments, as well as copper, nickel and platinum, to effect decomposition.

[99] See Gmelin, "Handbook of Chemistry," Translated by Watts, Cavendish Society, London, 1853, 8, 165; *Phil. Trans.*, 1809, 99, 446.

[100] *Crell's Annalen*, 1795, 2, 195, 310, 430.

[101] *Poggendorff's Annalen*, 1829, 16, 169.

[102] *J. prakt. Chem.*, 1842, 26, 478.

Later, Berthelot[103] found that ethylene passed through a tube heated to dull red heat was decomposed to ethane and acetylene. Marchand and Magnus[104] also detected the presence of methane in the product. DeWilde,[105] studying the effect of induced electric sparks on ethylene, obtained acetylene and hydrogen and later hydrogen and carbon.[106]

Day[107] circulated ethylene through a heated glass tube and found that decomposition accompanied by contraction in volume was noticeable at 350°-355° C., while polymerization was clearly indicated at 400°-408° C. At the latter temperature ethane and methane, but no hydrogen, were present in the reaction gas. In the same year Norton and Noyes[108] passed ethylene through a glass tube heated to a red heat and examined the products of reaction carefully. Carbon was deposited and benzene, naphthalene, and probably anthracene, were isolated from the liquid condensate. Only traces of acetylene were noted but from the bromination products of the reaction gas, propylene and butylene dibromide and butadiene tetrabromide were isolated. The formation of butadiene was assumed to occur according to the reaction:

$$2C_2H_4 \longrightarrow C_4H_6 + H_2$$

Bone and Coward[109] examined the decomposition of ethylene as well as that of other hydrocarbons. They circulated ethylene through a tube heated to 570°-580° C. for a period of 2½ hours and found that acetylene, ethane, methane, hydrogen, and aromatic hydrocarbons were produced and only a negligible amount of carbon was formed. At higher temperatures, methane, hydrogen, and carbon were the main products of reaction. It was concluded that acetylene was a principal product of the decomposition of ethylene. With ethylene and ethane it was supposed that the primary effect of high temperatures was to cause the elimination of hydrogen with simultaneous loosening, or dissolution, of the bond between the carbon atoms, labile residues such as $:CH_2$ and $\vdots CH$ being formed. These residues, assumed to possess a fugitive existence only, might subsequently either (a) form $H_2C{:}CH_2$ and $HC{:}CH$ by encounter between similar residues, or (b) break down directly into carbon and hydrogen, or (c) be directly hydrogenated to methane in an atmosphere already rich in hydrogen. For ethylene the scheme of decomposition is:

$$H_2C:CH_2 \longrightarrow 2(\vdots CH) + H_2 \longrightarrow \begin{array}{l} (a)\ C_2H_2 + H_2 \\ (b)\ 2C + 2H_2 \\ (c)\ + 2H_2 \longrightarrow \quad 2CH_4 \end{array}$$

Bone and Coward also stated that at comparatively low temperatures acetylene exhibits a strong tendency to polymerize to benzene, so that, whenever acetylene is a principal primary product of decomposition of another hydrocarbon (e.g., ethylene), there is always a marked secondary formation of aromatics at relatively low temperatures. Evidently, therefore, acetylene was regarded as an intermediate in the formation of aromatic hydrocarbons by pyrolysis.

Ipatiev[110] found that when ethylene was heated in an iron tube under high pressure, polymerization began at 325° C. and was rapid at 380°-400° C. The liquid products contained paraffin hydrocarbons from isopentane to nonane and cycloparaffins from nonanaphthene to pentadecanaphthene as well as amylene and hexylene. The fractions boiling above 250° C. were poorer in hydrogen so that evidently polymerization had been followed by other changes such as the splitting off of paraffins. Later, Ipatiev and Rutala[111] found that in the presence of anhydrous zinc chloride under a pressure of 70 atmospheres ethylene polymerized at 275° C. to various higher saturated and unsaturated aliphatic hydrocarbons together with various naphthenes.

Davidson,[112] as a result of an investigation of the thermal decomposition of the ethane-propane mixture of natural gas, assigned an important rôle to ethylene in the production of aromatic hydrocarbons. It was assumed that ethylene yielded butadiene, thus:

$$CH_2{=}CH_2 + CH_2{=}CH_2 \longrightarrow CH_2{=}CHCH{=}CH_2 + H_2$$

The condensation of another molecule of ethylene with butadiene would yield cyclohexene which probably had no separate existence, but broke down to benzene and hydrogen. In 1922 Zanetti, Suydam and Offner[113] studied the effect of temperature on the yield of butadiene. A stream of ethylene was passed through a tube (material unstated) at a constant rate of 7.8 liters per hour (heating duration, 0.8 min.). The proportion of butadiene formed reached a maximum of 0.96 per cent of the ethylene supplied at 750° C., its formation beginning between 550° and 600° C. and dropping off between 850° and 900° C. The falling off in the production of butadiene above 750° C. is coincident with the beginning of the formation of aromatics. From this it was suggested that the formation of aromatic hydrocarbons from ethylene takes place, at least in part, through the intermediate formation of butadiene. Williams-Gardner[114] also recognized that ethylene is important in the formation of aromatic hydrocarbons from ethane at temperatures above 750° C.

Walker[115] studied the reactions of ethylene at temperatures between 100° and 600° C. in the presence of various catalysts. In Jena glass in the absence of a catalyst ethylene was stable at temperatures below 600° C. Silica, silica gel plus borax, silica plus lime, lime, borax, calcium silicate, and zinc oxide were found to be inert towards ethylene up to 600° C. but ethylene reduced ferric oxide (Fe_2O_3) completely at 500° C., zinc oxide at 800° to 900° C., and lead oxide at 600° C. At temperatures from 100° to 550° C. ethylene was partly polymerized by metallic sodium to a colorless oil with gradual production of sodium ethylene carbide. Nickel and iron promoted the formation of carbon, hydrogen, and methane.

The thermal decomposition of ethylene in the presence of silica was studied by Hague and Wheeler.[116] Samples of ethylene were heated at different temperatures in quartz bulbs for three hours and the resultant gases analyzed. Between 400° and 700° C. the ethylene was found to polymerize, yielding butylene, the optimum temperature being 500° C. The results are given in Table 17.

Several "stream" experiments were carried out at 600°, 650°, and 700° C. and the resulting gases brominated yielding butylene dibromide and butadiene tetrabromide. Liquid hydrocarbons, principally aromatic, were obtained at the higher temperatures, the optimum temperature for their production being 750°-800° C.

[a] These figures for the acetylene content were too high. On passing some of the reaction gas through ammoniacal silver chloride only traces of precipitate were formed.

From a study of the non-catalytic pyrolysis of ethylene at 450° to 600° C. at ordinary pressure, Pease[117] concluded that butylene is the first product of the reaction. The precise nature of the reaction is not clear but it is probable, according to Pease, that molecular excitation and chain reactions play important rôles. Later, he[118] made a study of the kinetics of the polymerization of ethylene at 2.5, 5, and 10 atmospheres pressure in the temperature range 350° to 500° C. It was found that at least 50 per cent of the ethylene may be polymerized to gaseous and liquid monolefins without the formation of more than a few per cent of hydrogen and saturated hydrocarbons. The polymerization reaction, which is probably homogeneous, was found to be approximately bimolecular and to have a temperature coefficient of 2.3 per 25° C., which is abnormally low for this type of change.

Some of the data from the previously mentioned work of Schneider and Frolich[119] on the cracking of ethylene in silica tubes at a pressure of 0.2 atmosphere are shown in Figure 10. These results indicate that at zero reaction there are formed for each 100 moles of ethylene reacting about 41 moles of hydrogen, 36 moles of butadiene, 12 moles of propylene and 3 moles of butylene. They also indicate that about 72 per cent of the ethylene reacting forms butadiene and hydrogen as initial products:

$$2C_2H_4 \longrightarrow CH_2{=}CH{-}CH{=}CH_2 + H_2$$

Since a positive test for acetylene was always obtained, the excess of 5 moles of hydrogen may have come from a reaction producing acetylene. Ethane and methane were found to be definitely secondary products but it was observed that propylene was a primary pyrolytic product under the experimental conditions. This conclusion, though at first sight rather improbable, has been substantiated by the work of Lenher,[120] who found that propylene was the most important product of the polymerization of ethylene during the slow oxidation of ethylene with oxygen at temperatures of 450° to 520° C. A number of experiments with high ethylene concentrations and oxygen concentrations of about 5 per cent showed that below 520° C. propylene and butylene are the only hydrocarbons formed in oxygen-activated polymerizations. Thus, an experiment at 505° C. using a gas containing 87.0 per cent of ethylene and 8.8 per cent of oxygen and a time of reaction of 3.0 seconds, a 30.5 per cent yield of higher olefins was obtained. By careful analytical fractionation these were found to consist of 83 per cent of propylene and 14.6 per cent of butylene. A slow-oxidation experiment at 600° C. yielded a hydrocarbon product consisting of 59.3 per cent of propylene, 2.2 per cent of butylene, and 28.4 per cent of amylenes. In order to account for the formation of propylene as an initial product in the activated polymerization process Lenher advances three possible mechanisms (a) by intermolecular collision, (b) by the formation of an excited intermediate molecule C_4H_8' (not butylene) which then reacts with a further molecule of ethylene thus:

FIG. 10.—Pyrolysis of Ethylene (in Silica) at 725° C. and 0.2 Atmosphere. (Schneider and Frolich.)

$$2C_2H_4 \longrightarrow C_4H_8'$$
$$C_4H_8' + C_2H_4 \longrightarrow 2C_3H_6$$

and (c) the condensation of a free methylene radical with ethylene according to the scheme:

$$CH_2{=}CH_2 \longrightarrow 2(CH_2{=})$$
$$CH_2{=}CH_2 + (CH_2{=}) \longrightarrow CH_3CH{=}CH_2$$

Lenher considers that the last explanation is perhaps more probable than the others.

The production of liquid, mainly aromatic, hydrocarbons by the high temperature pyrolysis of ethylene has been studied by a number of workers including Smolenski,[121] Waterman and Tulleners,[122] Mailhe and Renaudie,[123] and Berl and Forst.[124] The last named employed a porcelain reaction tube at a temperature of 800° to 900° C. and obtained up to 43 per cent of liquid products containing aromatic hydrocarbons, benzene, naphthalene, and anthracene, as well as cyclopentadiene.

PROPYLENE

The pyrolysis of propylene in pyrex glass or quartz tubes at temperatures above 600° C. (below which temperature no change occurred even when the contact time was 50 seconds) was studied by Hurd and Meinert,[125] who concluded that the reaction was predominantly homogeneous and unimolecular. The products of pyrolysis consisted of hydrogen, methane, ethylene, and paraffin gases (chiefly ethane), while in certain experiments 20 to 25 per cent of the propylene was converted into a liquid of an aromatic nature. When pyrolyzed in monel metal tubes propylene was found to undergo profound decomposition even at temperatures as low as 350° C. and the products consisted largely of carbon and hydrogen. The reaction in monel metal tubes was found to be autocatalytic, the sooty carbon deposited on the walls of the tube at the beginning of the experiment accelerating the reaction so that it proceeded much more rapidly after 20 minutes.

Wheeler and Wood[126] studied the pyrolysis of propylene in a vertical quartz reaction tube at temperatures of 650° to 900° C. and found that liquid hydrocarbons could be obtained in yields as high as 40 per cent under certain conditions. The results of the experiments of these investigators are shown in Table 19.

C_4H_6	0.2	0.6	0.4	0.3		

The lower-boiling liquids obtained from the decomposition at 650° C. were mainly monocyclic hydroaromatic hydrocarbons with one double bond in the ring, while those produced at 700° C. were mainly benzene and toluene. At higher temperatures more complex aromatic hydrocarbons predominated in the liquid products. Wheeler and Wood concluded that one of the most important primary reactions occurring in the pyrolysis of propylene was its decomposition into equal molecular proportions of ethylene and butylene according to the equation:

$$2C_3H_6 \longrightarrow C_2H_4 + C_4H_8.$$

The work of Schneider and Frolich[127] has shed much light on the nature of the primary reactions occurring in the pyrolysis of propylene in silica reaction tubes at 725° C. The experimental results obtained at 0.2 atmosphere pressure are shown in Figure 11, from which it will be seen that at zero reaction about 48 per cent of propylene is converted into ethylene and butylene according to

FIG. 11.—Pyrolysis of Propylene (in Silica) at 725° C. and 0.2 Atmosphere. (Schneider and Frolich.)

the above reaction, while about 10 per cent goes to form butadiene and ethane according to the reaction:

$$2C_3H_6 \longrightarrow C_2H_6 + C_4H_6$$

Hydrogen, methane, and unsaturated hydrocarbons containing five and six carbon atoms are also formed as primary products, apparently by such reactions as

$$2C_3H_6 \longrightarrow C_5H_8 + CH_4 \quad \text{and} \quad 2C_3H_6 \longrightarrow C_6H_{10} + H_2$$

In spite of the fact that the above mechanism would indicate that propylene undergoes bimolecular reactions during pyrolysis, Schneider and Frolich confirm the conclusion of previous workers that the cracking reactions behave approximately as first order homogeneous gas reactions.

The production of liquid hydrocarbons by pyrolysis of propylene in the presence of silica gel at 650° C. and 700° C. has been studied by Mailhe and Renaudie,[128] who found that the liquid condensate contained low-boiling olefins, benzene, toluene, and m-xylene, as well as more complicated polynuclear aromatic hydrocarbons.

Groll,[129] from a study of the pyrolytic conversion of ethylene, propylene, propane, n-butane, isobutane, and 2-butene at about 800° C., observed that propylene yielded the highest proportion of aromatic hydrocarbons. Diminished pressure and reaction time and lower temperature favor the formation of acetylene.

BUTYLENES

The pyrolysis of the two straight-chain isomers, 1-butene and 2-butene, in vertical silica reaction tubes and at atmospheric pressure has been studied by Wheeler and Wood.[130] The decomposition products of the two isomers were similar, though 2-butene was somewhat more stable than 1-butene.[131] Approximately equal volumes of methane and propylene were produced at 600° C., indicating that a probable primary reaction was the rupture of the terminal carbon-carbon bond, followed by hydrogenation of the radicals so formed. The hydrogen necessary for the latter process was believed to come from the simultaneous formation of butadiene according to the equation:

[131] To convert 1-butene to 2-butene, Runge and Mueller-Cunradi (U. S. Patent, 1,914,674, June 1933; assigned to I.G. Farbenindustrie A.-G.; *Chem. Abs.*, 1933, **27**, 4253) proposed heating at

$$C_4H_8 \longrightarrow C_4H_6 + H_2$$

Large quantities of liquid products were formed during the pyrolysis of these butenes, oil formation being at a maximum at about 750° C. The liquid products formed at lower temperatures (600° C.) contained large proportions of cyclohexene and cyclohexadiene hydrocarbons, particularly the former, but benzene and toluene were present in comparatively small amounts. At higher temperatures the liquid products were predominantly aromatic in character. The results of Wheeler and Wood on the pyrolysis of 1-butene and 2-butene are summarized in Table 20.

In the presence of silica gel at 650° to 700° C., 1-butene formed liquid unsaturated hydrocarbons and benzene, toluene and m-xylene, together with 40 per cent (by volume) each of propylene and methane, according to Mailhe and

---

550° C. in an empty quartz tube or at 420° C. in contact with calcium oxide, aluminum phosphate on pumice or bauxite. Temperature has been shown to play two rôles in this isomerization: it changes the rate and permanently changes the power of the catalyst, according to Matignon, Moureu, and Dodé (*Compt. rend.*, 1933, **196**, 973, 1560; *Chem. Abs.*, 1933, **27**, 2934, 3910).

Renaudie.[132] 2-Butene at a higher temperature yielded somewhat more benzene and toluene in addition to naphthalene and anthracene.

A study of the pyrolysis of isobutylene was made by Hurd and Spence,[133] who subjected this hydrocarbon to thermal treatment in pyrex glass tubes at 600° to 700° C. Isobutylene was found to be much more stable thermally than isobutane and its decomposition was very slow at 600° C. In other respects, the reactions of these two hydrocarbons were also materially different. Isobutane decomposed initially into gaseous hydrocarbons of lower molecular weight, but isobutylene, on the contrary, gave higher molecular weight hydrocarbons. Thus, nearly half of the decomposed isobutylene was converted into liquid hydrocarbons, the remainder appearing as gaseous products. Table 21 gives some of the results of Hurd and Spence on isobutylene.

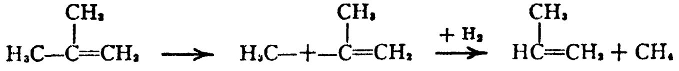
TABLE 21.—*Decomposition of Isobutylene in Pyrex Glass Tubes.*

			Cc. Gaseous Products per Liter Isobutylene Decomposed						Oil Yield
Temp. ° C.	Contact Time Sec.	% Decom-position	C_3H_6	CH_4	Iso-C_4H_{10}	H_2	C_2H_2	C_2H_4+ Aro-matics	% Iso-butylene Decom-posed
599	200	20	305	590	270	175	15	90	—
652	27	22.7	172	286	176	150	35	31	39.6
652	13	11.1	144	135	198	54	108	99	63
700	12	30.2	218	586	133	242	43	66	46.6
700	18	47.7	228	655	61	260	59	69	63

It is remarkable that no butadiene was found in the gaseous reaction products. An examination of the liquid products obtained at 700° C. showed that these consisted chiefly of aromatic hydrocarbons, benzene and toluene having been identified and the probable presence of xylene, naphthalene, anthracene, and phenanthrene indicated. The fraction boiling up to 76° C. gave evidence of containing appreciable amounts of unsaturated hydrocarbons. The decomposition of isobutylene was found to be homogeneous and unimolecular.

Hurd and Spence suggest, as the mechanism of the reaction, that heat may rupture the C—C or C—H bonds, and that it may activate the C=C double bond. The double bond is considered sufficiently strong to resist complete rupture, thereby creating a radical with two free bonds. Three such "activated" olefin molecules from isobutylene, that is, $(CH_3)_2\overset{|}{C}—\overset{|}{C}H_2$, would, by combination, produce a cyclohexane derivative, which, at the elevated temperature of formation, would be dehydrogenated into benzene derivatives.

It seems more than likely, however, that at least one of the reactions taking place in the thermal decomposition of isobutylene (judging from the production of propylene and methane) is the formation of free radicals (one of which is the methyl radical) followed by hydrogenation by the hydrogen derived from another phase of the process thus:



$$H_3C—\overset{\overset{CH_3}{|}}{C}=CH_2 \longrightarrow H_3C—+—\overset{\overset{CH_3}{|}}{C}=CH_2 \xrightarrow{+H_2} H\overset{\overset{CH_3}{|}}{C}=CH_2 + CH_4$$

[133] *J.A.C.S.*, 1929, 51, 3561: the pyrolysis of isobutylene was also investigated by Noyes (*Mass. Inst. Technology Quarterly*, 1888, 1, 278), Nef, (*Ann.*, 1901, **318**, 24), Lebedev and Kobliansky (*Ber.*, 1930, **63**, 103, 1432), Ipatiev (*Ber.*, 1903, **36**, 2003), and by Ipatiev and Sdzitovecky (*J. Russ. Phys.-Chem. Soc.*, 1907, **39**, 897).

Pentenes

Of the pentenes studied, trimethylethylene appears to be the most stable and isopropylethylene the least so. Norris and Reuter[134] showed that isopropylethylene undergoes isomerization to trimethylethylene to the extent of 10 per cent when heated in a silica tube containing alumina for 16 seconds at 450° C. With a similar heating period, the isomerization was 29 per cent in the presence of phosphoric acid at 500° C., and 47 per cent in the presence of aluminum sulphate at 425° C. Under similar conditions neither trimethylethylene nor 2-pentene undergo any change. Previously, Ipatiev[135] reported that isopropylethylene is isomerized to trimethylethylene to the extent of about 80 per cent by exposure to silica at 500° to 505° C. or to alumina at 525° to 535° C.

The decomposition of 2-pentene in silica tubes at 600° C. was investigated by Norris and Reuter,[136] who obtained the following proportions of products in percentages by weight: 2-pentene, 33%; hydrocarbons of higher molecular weight, 15%; methane, 7.8%; butadiene, 8%; butylene, 8%; propylene, 4%; ethylene, 2%. Some carbon was deposited in the reaction tube but no free hydrogen was found among the products. In the mixture of hydrocarbons of molecular weights lower than 2-pentene, the components were present in the following approximate molecular ratio: methane, 100; butadiene, 27; propylene, 21; ethylene, 15.

An interpretation of these results is necessarily difficult on account of the complexity of the products but it is evident that polymerization, demethanation, and dehydrogenation proceed simultaneously. Since the number of molecules of methane was approximately equal to the number of molecules of other hydrocarbons present, loss of a methyl group can be assumed with subsequent hydrogenation of the unsaturated residues formed thus:

$$CH_3CH_2CH{=}CHCH_3 \longrightarrow CH_3CH_2CH{=}CH{-} + CH_3{-}$$
$$\xrightarrow{H_2} CH_3CH_2CH{=}CH_2 + CH_4$$

The hydrogen necessary for the latter process was presumably produced partly from decomposition of hydrocarbons with deposition of carbon and partly from the dehydrogenation of butylene to give butadiene thus:

$$CH_3CH_2CH{=}CH_2 \longrightarrow CH_2{=}CHCH{=}CH_2 + H_2$$

Pyrolysis of 2-pentene in the presence of silica gel in a quartz tube at 670° C. was found by Mailhe and Renaudie[137] to yield a gas consisting of 52 per cent propylene and butylene, 34 per cent methane and 6 per cent hydrogen, together with oil and tar. At the same temperature isopropylethylene yielded 47 per cent ethylene homologues, 38 per cent methane, 7 per cent hydrogen, and oil and tar.

Norris and Reuter examined the pyrolysis of trimethylethylene at a temperature of 650° C. under conditions similar to those used with 2-pentene. As before, no free hydrogen was produced and the products of decomposition consisted of one-third higher molecular weight substances and two-thirds of substances of lower molecular weight with methane making up about 50 per cent of the gases formed. Here again, demethanation followed by hydrogenation of the residues would suffice to explain part of the decomposition process thus:

---

$$H_3C-\overset{CH_3}{\overset{|}{C}}=CHCH_3 \longrightarrow H_3C-\overset{CH_3}{\overset{|}{C}}=CH- + -CH_3 \xrightarrow{+H_2} H_3C-\overset{CH_3}{\overset{|}{C}}=CH_2 + CH_4$$

No 1,3-butadiene was observed in the reaction gas, which is in agreement with the theory since isobutylene could not be dehydrogenated to 1,3-butadiene without rearrangement.

Staudinger, Endle and Herold[138] studied the pyrolysis of trimethylethylene at 750° C. at atmospheric pressure and also under reduced pressure. Working at 15 mm. pressure, 50 grams of trimethylethylene yielded 8.3 grams of isoprene, 0.2 gram of butadiene and about 1.1 grams of ethylene together with some propylene. An earlier investigation of Haber and Oechelhäuser[139] on the pyrolysis of this amylene at temperatures from 600° to 1060° C. in porcelain tubes showed that at lower temperatures (750°-790° C.) the gaseous products consisted mainly of ethylene and methane. At higher temperatures (1050°-1060° C.) the gaseous products contained 50 per cent hydrogen, 30 per cent methane, and only 5 per cent ethylene, heavy aromatic tars being also formed.

Of considerable scientific interest is the work of Norris and Thomson,[140] who made a careful determination of the temperatures at which 1-pentene, 2-pentene, and trimethylethylene begin to decompose when heated in a Pyrex glass vessel for one hour. The observed initial cracking temperatures of 1-pentene, 2-pentene, and trimethylethylene were about 389° C., 400° C., and 433° C., respectively, while breaks in the curves at 420° C., 421° C., and 488° C., respectively, indicated that a second type of cracking reaction takes place at these temperatures. Above a certain temperature the rates of expansion of the heated vapors of each hydrocarbon either remained constant or decreased as the temperature was raised, indicating that both pyrolysis and polymerization reactions were then taking place. It was found that a trace of moisture doubled the rate of cracking of 2-pentene at temperatures just above the initial cracking temperature, which was not, however, altered by such addition of water vapor.

Higher Olefins

Hurd and Bollman[141] studied the pyrolysis of diallyl, 4-methyl-1-pentene, allylcyclohexane, and 4-phenyl-1-butene. In contrast to propylene and isobutylene,[142] which require temperatures of 700° C. or above for extensive decomposition, these olefins decomposed considerably in the range of 425° to 500° C. A predominating proportion of propylene with no allene and only a small proportion of ethylene was formed. In every case high-boiling polymerization products were also encountered. Hurd and Bollman explain these facts by assuming that α-olefins undergo a preliminary scission into radicals at the allyl bond:

$$R-C_3H_5 \longrightarrow R- + C_3H_5-$$

These radicals then acquire hydrogen atoms from some source, presumably largely from the original hydrocarbon, and escape as RH + C_3H_6. The dehydrogenated material may undergo polymerization, in common with the original unsaturated hydrocarbon. From this work they conclude that simple scission into two compounds (such as that of n-butane into ethane and ethylene or methane and propylene) should not be considered the primary effect, even though each of them may be found in the reaction products.

Hugel and Szayna[143] studied the pyrolysis of a mixture of straight-chain octenes (consisting essentially of 40 per cent 1-octene and 60 per cent 2-octene) in quartz tubes over the temperature range 290° C. to 600° C. The lowest temperature at which any change was detected was about 365° C. where the reaction products had a wider boiling range (117° to 130° C.) than the initial material (boiling range 121.5° to 124° C.), though no appreciable evolution of gas occurred. This effect was presumed to be due to isomerization of the straight-chain octenes to branched-chain isomers of lower boiling points.[144] Above 400° C., part of the octene decomposed with production of gas and a low-boiling liquid as well as some tar and carbon. The low-boiling liquid produced at 440° C. showed indications of the presence of unsaturated cyclic hydrocarbons while that obtained by pyrolysis at 540° C. and 600° C. contained benzene. The composition of the gaseous products of cracking at various temperatures is summarized in Table 22.

TABLE 22.—*Gaseous Products of Pyrolysis of Octene in Silica Tubes.*

Temp. ° C.	Gas Produced in Moles per Mole of Octene Decomposed	Gas Analysis (per cent by volume) Paraffins	Olefins	Acetylenes (?)	H_2

480°-490°	1.54	73	17.5	3	6.5
540°-549°	2.63	69	19.5	5	6.5
600°	2.70	67	15	4.5	13.5

A comprehensive examination of the thermal decomposition of hexadecene at atmospheric, and also at superatmospheric pressures, has been made by Gault and his collaborators.[145] Hexadecene, prepared by the distillation of cetyl palmitate under diminished pressure, was subjected to pyrolysis in the absence of catalysts at temperatures of 350° to 725° C. The gaseous products of cracking contained a maximum of 66 to 68 per cent unsaturated hydrocarbons at 575° to 600° C., this optimum production of unsaturated gases being coincident with a minimum (about 26 per cent) content of saturated gaseous hydrocarbons. As the temperature of the decomposition was raised the proportion of saturated gaseous hydrocarbons increased, that of unsaturated gases diminished, and the yield of hydrogen, which appeared at the beginning of the pyrolysis, increased with rising temperature. Ethylene, propylene, butylene, amylene, and butadiene were identified in the gaseous products of cracking by means of their bromine addition compounds. The proportion of butadiene in the gaseous products varied from 4 per cent to 7 per cent and reached a maximum at about 500° C., being equal at this temperature to about 1 per cent of the original hexadecene. At 600° C. and over, some carbon was deposited and aromatic hydrocarbons began to preponderate in the liquid products. It was considered by these investigators

[143] *Ann. combustibles liquides,* 1926, 1, 781.

[144] Numerous cases of the isomerization of monolefins under the influence of heat have been reported, especially in the presence of catalysts. Among the higher monolefins, 2,6-dimethyl-7-octene has been shown to be completely isomerized to 2,6-dimethyl-6-octene in the presence of palladized asbestos at 200° C. in the vapor phase (Zelinsky and Levina, *Ber.,* 1929, **62**, 1861.

[145] Gault and Altchidjian, *Compt. rend.,* 1924, **178**, 2092; *Ann. chim.,* 1924, (10) **2**, 209; Gault, Hessel and Altchidjian, *Compt. rend.,* 1924, **178**, 1562.

that the main steps in the pyrolysis of hexadecene at atmospheric pressure consisted in the splitting off of methane from the ends of the hexadecene molecule, the olefinic residues thus formed subsequently undergoing further disintegration into smaller fragments. Hugel and Goldthorpe[146] showed that, in the presence of nickel-impregnated pumice at 350° C., hexadecene undergoes rapid decomposition with a copious production of free carbon. A similar result was obtained using iron-pumice catalyst at 425° C., although with pumice alone carbon deposition was first noticeable at 500° C.

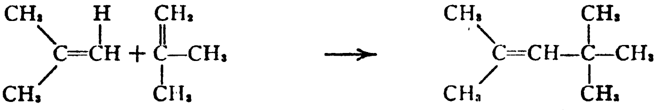
Pyrolysis of Olefins Under Pressure

Before leaving the subject of the thermal decomposition of the olefins, reference must be made to work carried out on the effect of heating olefins under pressure. In this connection the work of Ipatiev on the high pressure condensation of ethylene at temperatures above 325° C. has already been discussed.

Ipatiev[147] also studied the effect of heating isobutylene in a closed tube at 380° to 390° C. The gaseous products consisted of 10.8 per cent hydrogen, 69.6 per cent C_nH_{2n} hydrocarbons, and 20.1 per cent C_nH_{2n+2} hydrocarbons. The oil obtained from 500 grams of isobutylene distilled as follows:

° C.	Grams	° C.	Grams
23–100	70	215–260	82
100–150	105	260–280	55
150–190	55	Over 280	60
190–215	58		

Paraffins and olefins were present in the lower-boiling fractions and cycloparaffins as well as olefins and hydrocarbons deficient in hydrogen were found in the higher fractions. No aromatic hydrocarbons were identified. It would appear that polymerization of the olefin to di- and tri-isobutylene and higher polymers occurs first, followed by decomposition and cyclicization of the polymers. The first stage of the polymerization reaction may probably be written:



Diisobutylene

Engler and Rutala[148] studied the effect of heating amylene in a sealed tube. Heating at 230° C. for eleven days raised the specific gravity from 0.6647 to 0.6725 and halved the bromine absorption, and heating for twelve days at 300° C. raised the specific gravity from 0.6647 to 0.7505. By heating 350 grams of commercial amylene for 32 days at 325° C. ten liters of permanent gas containing 10 per cent of hydrogen, 1.5 per cent of hydrocarbons having the formula C_nH_{2n}, and 91.1 per cent of hydrocarbons having the formula C_nH_{2n+2}, were produced as well as a liquid having a bluish-green fluorescence and a terpene-like odor. The higher-boiling fractions were rich in olefin hydrocarbons, which were removed from the oil by fuming sulphuric acid. The resulting olefin-free oil was fractionated, and the following hydrocarbons were shown to be present: pentanes, hexanes, heptanes, cyclohexane, methylcyclopentane, heptanaphthene, octane, octanaphthene, nonanaphthene, decanaphthene, undecanaphthene, dodecanaphthene, tetradecanaphthene, pentadecanaphthene, and higher-boiling cycloparaffins (as well as hydrocarbons more deficient in hydrogen in the highest-boiling fractions).

---

[146] *Ann. combustibles liquides*, 1928, 3, 613.
[147] *Ber.*, 1911, 44, 2978.
[148] *Ber.*, 1909, 42, 4620.

Engler and Eberle[149] heated a hexylene (consisting of a mixture of 1-, 2-, and 3-hexenes;[149a] b.p. 67°-68° C.; d_{15}^{15} 0.687) for 14 days in a sealed tube at 360° to 365° C. The product boiled between 67° C. and 240° C. and had a lower bromine absorption (especially in the higher fractions) than the original hexylene. Low-boiling paraffins and cycloparaffins, such as cyclohexane and dodecanaphthene, were present and the higher fractions were poorer in hydrogen than a substance of the formula C_nH_{2n}. It was concluded that besides polymerization of the hexylene to higher olefins, cyclicization to cycloparaffins and subsequent decomposition of the higher polymers to substances both richer (i.e., paraffins) and poorer in hydrogen had taken place.

A comprehensive study[150] of the reactions induced by heating hexadecene under pressure at a temperature of about 300° C. showed that polymerization to higher monolefins, $C_{32}H_{64}$ and $C_{48}H_{96}$, was the predominant process especially in the absence of a gaseous phase. As might be expected, the polymerization reactions were greatly accelerated by higher pressures and a study of the process as a function of time indicated that it was probably an equilibrium dependent upon the pressure and temperature.

The effect of heat and pressure on a vapor phase cracked gasoline has been investigated by Payne and Lowy.[151] The gasoline was produced by cracking a light solar oil at 600° C. under a pressure of 100 pounds per square inch for 10 minutes. Some of the gasoline distillate so obtained was heated at 300° C. under 68 atmospheres pressure for 6 hours in a steel bomb. Analyses of the original and heat-treated distillates indicated that not only had a decrease in the percentage of olefin hydrocarbons been effected, but also an increase in the percentage of naphthenes. (See Table 23.)

TABLE 23.—*Effect of Heat and Pressure on Vapor Phase Cracked Gasoline.*

	Original Distillate to 201.5° C.	Treated Distillate to 201.5° C.
	Per Cent	
Olefins	35.0	24.5
Aromatics	17.0	15.5
Naphthenes	25.9	34.2
Paraffins	22.1	25.8

Both the original and heat-treated gasolines were distilled and fractions taken approximately every 5.5° C., up to 201.5° C., and the fractions analyzed. It was observed that heat treatment had decreased the percentage of unsaturated hydrocarbons in the various fractions but had increased the percentage of naphthenes. Polymerization was thought to be responsible for the larger proportion of the distillate boiling above 201.5° C. after the heat treatment as well as for the disappearance of cycloalkenes and the formation of hydrocarbons containing hydrogen atoms easily replaceable by halogens (as indicated by the Johansen iodine substitution value).

DIOLEFINS

The thermal behavior of the diolefin hydrocarbons has been but little studied. In the past, attention has largely been concentrated on the polymerization of conjugated diolefins under the influence of heat, with or without catalysts, to liquid, resinous, and rubber-like polymers (see Chapter 26). Cyclic unsaturated dimers (polymers of two molecules of the original substance) are principally obtained by heating these diolefins alone in sealed tubes at temperatures below 300° C. Little has been reported on the pyrolysis of non-conjugated diolefins. The thermal decomposition of both conjugated and non-conjugated diolefins deserves much more attention, since the former, particularly 1,3-butadiene, seem to be important in the production of aromatic from aliphatic hydrocarbons.

Staudinger, Endle and Herold[152] examined the pyrolytic decomposition of isoprene, butadiene, and 2,3-dimethyl-1,3-butadiene. It was found that isoprene was partly polymerized at 400°-500° C., yielding terpene-like products together with amylene. Between 600° and 700° C. complete decomposition occurred and ethylene, propylene, and butadiene were present in the gaseous products. Above 700° C. aromatic hydrocarbons appeared and at 750° C. and 800° C. aromatic hydrocarbons were formed almost exclusively. Thus, at 750° C. isoprene yielded 44 to 55 per cent of a tar closely resembling coal tar and containing benzene, toluene, naphthalene, anthracene, and higher aromatics. The gaseous products contained butadiene, hydrogen, methane and ethylene, and carbon was deposited in the reaction chamber.

Butadiene at 750° C. gave a mixture of aromatic hydrocarbons. At 800° C., using a quartz tube packed with coke, butadiene produced benzene, saturated liquid hydrocarbons, naphthalene, and anthracene. Similarly, 2,3-dimethylbutadiene at 800° C. yielded aromatic hydrocarbons.

SUMMARY OF THERMAL REACTIONS OF OLEFIN HYDROCARBONS

Our knowledge of the mechanism of the thermal reactions of the olefin hydrocarbons is exceedingly scanty and only the simplest member, namely ethylene, has been examined in any detail. It appears, however, that the olefins are sharply differentiated from the corresponding paraffin hydrocarbons by the fact that, whereas the latter decompose initially with the production of substances of lower molecular weight only, the olefins tend to produce, partly at any rate, quantities of higher molecular weight hydrocarbons, and at the same time some decomposition to lower molecular weight substances also takes place.[152a] Olefin hydrocarbons, in general, are more rapidly decomposed than paraffins, this difference becoming less, however, with increasing molecular weight of the compounds.[153]

The synthesis of higher hydrocarbons from olefins by pyrolysis probably occurs in the first place by a simple polymerization to produce a higher olefin. Thus, ethylene yields butylene, and isobutylene, diisobutylene. The polymerized olefin can, however, undergo decomposition in several ways so that the reaction products tend to become complex. The polymerization of olefins to produce higher olefins is possible thermodynamically up to 500° C. as has been shown by Sachanen and Tilicheyev.[154] There is no doubt that this process affords an explanation of the production of larger molecules from olefins in thermal decomposition. The application of pressure tends naturally to favor polymerization, as confirmed by the work of Ipatiev and others.

---

[152] *Ber.*, 1913, **46**, 2466.

[152a] Hurd (*Ind. Eng. Chem.*, 1934, **26**, 50) reviewed the work on pyrolysis of unsaturated hydrocarbons and placed the reaction products into the groups: Simple products with lower boiling points than the original substances, isomers and dehydrogenation products in the same distillation range as the original hydrocarbons, and polymers with higher boiling points than the original substance. He stated that contact time is more important than size of tube or rate of flow of the gas through the tube in pyrolysis.

[153] Tilicheyev and Feigin, *Rept. Conf. Cracking Hydrog. Grozni*, 1931, 1, 267; *Brit. Chem. Abs.* **B**, 1932, 456; *Chem. Abs.*, 1932, **26**, 1105.

The polymers so formed might be expected to be monolefins having molecular weights which are simple multiples of that of the parent material. There is much evidence in support of this supposition, particularly in thermal reactions carried out under pressure and at moderate temperatures, e.g., the thermal treatment of hexadecene at 300° C. under pressure yields monolefinic polymers of the type $(C_{16}H_{32})x$, where x is a simple whole number. In the high-temperature pyrolysis of the simple monolefins such as ethylene, it has usually been assumed that thermal polymerization gives rise initially to polymers of this type. Certain work, however, particularly that of Schneider and Frolich, and also of Lenher, appears to indicate that reactions of the type

$$3C_2H_4 \longrightarrow 2C_3H_6,$$

e.g., the transformation of ethylene to propylene and not to butylene, can take place. The mechanism of such reactions is still very obscure.

Though polymerization reactions are essentially favored by low temperatures and the presence of catalysts, they play an important rôle in the pyrolysis of olefins even at elevated temperatures and in the absence of catalysts.

Isomerization of olefins to five- and six-membered cycloparaffins is possible thermodynamically up to about 500° C., though Sachanen and Tilicheyev consider that in commercial cracking operations the velocity of this reaction is too small to yield appreciable quantities of cycloparaffins. In the presence of catalysts, however, such as aluminum chloride, this isomerization can undoubtedly take place.

Besides polymerization to higher olefins and isomerization to cycloparaffins, the olefin can also, in part, undergo decomposition with the production of lower hydrocarbons. The exact mode of scission is doubtful but this can probably take place in several ways. Thus, an olefin molecule can break down to form two lower olefins (a change analogous to depolymerization) or a paraffin hydrocarbon can be split off and a diolefin produced. By the first reaction amylene would yield ethylene and propylene, while by the second, methane and butadiene would result thus:

$$(1)\ CH_3CH_2CH_2CH{=}CH_2 \longrightarrow CH_3CH{=}CH_2 + CH_2{=}CH_2$$
$$(2)\ CH_3CH_2CH_2CH{=}CH_2 \longrightarrow CH_4 + CH_2{=}CHCH{=}CH_2$$

The primary reactions in the thermal decomposition of olefins may then be considered to be:

(1) Polymerization to higher olefins.
(2) Decomposition with the production of lower olefins, paraffins, and diolefins.

It appears from the work of Schneider and Frolich that some of the primary reactions of the olefins are much more complicated than was hitherto believed. For example, the most important primary reaction occurring in the non-catalytic pyrolysis of ethylene at 725° C. is one in which butadiene and hydrogen are formed (apparently without the intermediate production of butylene), according to the equation:

---

[154] *Ber.*, 1929, 62, 658.

$$2C_2H_4 \longrightarrow C_4H_6 + H_2$$

It should be pointed out, however, that the formation of butylene as a transitory intermediate product in this reaction is not entirely disproved by the work of Schneider and Frolich and that at lower temperatures the reaction given above may be found to consist of two consecutive reactions; namely, polymerization to butylene and subsequent dehydrogenation of the butylene. Certainly it is difficult to visualize the exact mechanism of the change as written in the above equation.

Finally an initial stage in the pyrolysis of olefins may be isomerization to a more stable unsaturated hydrocarbon. As the temperature rises the primary pyrolytic reactions, which are different for individual olefins, are obscured by secondary changes which appear to be the same for almost all olefins. These secondary reactions yield aromatic hydrocarbons and hydrogen. Hague and Wheeler and a number of prior workers consider that aromatic hydrocarbons are produced from olefins through the formation of butadiene. Thus, ethylene by polymerization gives butylene which loses hydrogen and is converted into butadiene. A continuation of this process suffices to yield hexatriene, which can be supposed to yield benzene by loss of hydrogen.

THERMAL DECOMPOSITION OF ACETYLENE

The pyrolysis of acetylene is of importance in the study of the thermal reactions of hydrocarbons especially from the point of view of the importance assigned to it as an intermediate product by various workers, more especially by Berthelot, who regarded acetylene as the fundamental source of all synthetic processes during pyrolysis. The great importance assigned to acetylene in the building up of larger molecules during pyrolysis has been to some extent discounted by later research, which has directed attention to the important functions of the olefins and diolefins. Nevertheless, it appears that acetylene is, in some cases, to be regarded as a source of the aromatic hydrocarbons formed during pyrolysis, especially from the decomposition of methane at very high temperatures. Acetylene is of great interest also on account of the fact that its stability at very high temperatures is greater than that of any other volatile hydrocarbon. Thermodynamic calculations indicate that acetylene cannot be formed in any amount in the pyrolysis of hydrocarbons at temperatures below 850° C.

Bone and Coward[155] showed that at 500° C. and 600° C. the non-catalytic thermal decomposition of acetylene resulted mainly in formation of polymers and to a lesser extent in decomposition into its elements. Reactions of less importance are hydrogenation to ethylene, ethane, and methane. At higher temperatures polymerization occurs to a minor extent and decomposition into carbon and hydrogen and production of methane predominates. The most favorable temperature range for condensation of acetylene is 600° to 700° C.

The pyrolysis of acetylene to produce higher hydrocarbons (principally aromatic) has been noticed by a large number of investigators, particularly by Meyer and his co-workers,[156] who isolated the following hydrocarbons from the products of pyrolysis: hexene, benzene, toluene, o-, m-, and p-xylenes, styrene, pseudocumene, mesitylene, indene, hydrindene, naphthalene, hydronaphthalene,

---

[155] *J.C.S.*, 1908, 93, 1197.

[156] *Ber.*, 1912, 45, 1609; 1913, 46, 3183; 1914, 47, 2765; 1917, 50, 422; 1918, 51, 1571.

1- and 2-methylnaphthalenes, 1,4-dimethylnaphthalene, diphenyl, acenaphthene, fluorene, anthracene, phenanthrene, fluoranthrene, pyrene, and chrysene.

Zelinsky[157] obtained a yield of 76 to 80 per cent of tar calculated on the weight of acetylene used by passing acetylene over activated wood charcoal at 640°-650° C. Benzene was found to be the most important constituent of the tar, and toluene and xylene were present in smaller amounts. About 35 per cent of the tar was benzene, 4 per cent toluene, 6.7 per cent naphthalene, 1 per cent fluorene and anthracene, and 0.4 per cent p-xylene, styrene, and indene.

The polymerization of acetylene has been investigated by Fischer, Bangert and Pichler.[158] They found that on passing acetylene over activated charcoal or silica gel at 600°-700° C., hydrogen, methane, and carbon are formed. The carbon which was thus deposited acted as a polymerization catalyst, the proportion of liquid hydrocarbons increasing until about 70 per cent of the acetylene was converted to light and heavy oils. The light oil (boiling up to 150° C.) contained 70 per cent aromatic and 30 per cent unsaturated hydrocarbons. The exhausted catalyst could be regenerated by the addition of carbon dioxide to the acetylene, this admixture also serving to increase the production of light oil. Low pressures did not increase the efficiency of the process.

According to Pease,[159] in the pyrolysis of acetylene, polymerization is the only reaction of importance at temperatures up to 600° C. The reaction is homogeneous and bimolecular and is retarded by packing the reaction tube with glass. Schläpfer and Brunner[160] concluded that the thermal polymerization of acetylene in glass tubes, which begins at 300° C. but does not become rapid until a temperature of 450° C. is attained, is homogeneous and probably bimolecular. Increased glass surface has little effect on the reaction velocity, but copper accelerates and iron powder or carbon retards the rate of polymerization. Fukagawa[160a] found that, in the presence of reduced nickel, the temperature of maximum thermal polymerization rises with repeated use of the catalyst and that the optimum temperature was below 300° C.

The polymerization of acetylene to benzene is an exothermic process and the reaction is, therefore, likely to become a spontaneously explosive decomposition. In order to control the reaction to form aromatic hydrocarbons, Berl and Hoffman[161] used carbon dioxide as a diluent for absorbing the heat and obtained a 98 per cent yield of liquid products using a carbon catalyst at 600°-700° C. Iron, silica, and acid or alkaline contact masses (e.g., tin or calcium oxides) were unfavorable to the production of liquid products but the yield of the latter was improved by charging the gas with water vapor.

The thermal reactions of acetylene may be summarized as follows: At temperatures up to 700° C. the main reaction is that of condensation to liquid and solid hydrocarbons, mostly aromatics, and decomposition into its elements is of secondary importance. At higher temperatures the polymerization reaction is suppressed and the formation of carbon and hydrogen predominates. At very high temperatures, however, acetylene becomes more stable with respect to decomposition.

PYROLYSIS OF NON-AROMATIC CYCLIC HYDROCARBONS

Hydrocarbons possessing a closed ring of carbon atoms but lacking the peculiar properties of aromatic compounds are known as cycloparaffins, polymethylenes and naphthenes. The latter term is loosely used, however, to designate all cyclic hydrocarbons (other than aromatics), more particularly those found in various petroleum fractions. Various polynuclear naphthenes are known but their modes of decomposition on pyrolysis have been little investigated. The term cycloparaffins, which indicates their cyclic saturated character, is perhaps preferable and will be used to designate hydrocarbons of this class.

Calculations of the stability of monocyclic saturated hydrocarbons on the basis of the Baeyer strain theory indicate that five- and six-membered carbon ring systems (and particularly the former) should be the most stable. In agreement with this, it has been found that cyclopentane and cyclohexane derivatives predominate among the naphthene hydrocarbons of crude petroleum. Chemical evidence in the main is in agreement with Baeyer's theory, thus ring systems containing 2, 3, 4, 7 or 9 carbon atoms being rather unstable, and those containing 5 and 6 carbons are relatively stable. Yet Ruzicka[162] has shown that systems containing 10 to 30 carbons are surprisingly stable. Furthermore, the naturally occurring compound, civetone (the active odorous principal in civet) is an unsaturated cyclic ketone with 17 carbon atoms, hydrogenation of which yielded dihydrocivetone which proved to be identical with cycloheptadecanone synthesized by Ruzicka.

The tendency of cyclohexane derivatives to lose hydrogen at fairly low temperatures in the presence of catalysts and form principally benzene derivatives was first demonstrated by Sabatier and Senderens.[163] Cyclohexane in the presence of nickel at 270°-280° C. was found to yield benzene but some methane was also formed. Substituted cyclohexanes and hydronaphthalenes behaved in a similar way. Reduced copper was somewhat less active as a catalyst in promoting this change, dehydrogenation of cyclohexane beginning at 300° C.

CYCLOPROPANE, CYCLOBUTANE AND CYCLOPENTANE

Cycloparaffins with rings of less than 5 carbon atoms appear to isomerize partly into the corresponding olefin under the influence of heat. Thus Tanatar[164] reported that when trimethylene (cyclopropane) was passed slowly through a glass tube heated to a dull red heat, it was converted to propylene. At 100° C. in the presence of platinum black a 40 per cent conversion was obtained.

Ipatiev and Huhn[165] observed very little isomerization of cyclopropane when the gas was passed slowly through a heated glass tube without a catalyst. At 200° C. in the presence of platinum sponge a 5 per cent conversion was noted, and at 315° C., 29 per cent conversion was obtained. When an aluminum oxide catalyst was used at a temperature of 370°-385° C., a 20 per cent conversion to propylene took place. 1,1-Dimethylcyclopropane passed over an aluminum oxide catalyst at 340°-345° C. was almost completely converted to trimethylethylene.

The isomerization of methylcyclopropane to 2-butene and isobutylene has been reported by Dojarenko,[166] and that of ethylcyclopropane to methylethylethylene by Rozanov.[167] In both instances aluminum oxide was used as the catalyst.

Trautz and Winkler[168] studied the kinetics of this isomerization and found it to be a unimolecular reaction. At high temperatures (700° C.) and with long times of contact, however, the formation of secondary products, hydrogen and methane, from propylene takes place. Methylenecyclopropane[169] is said to yield 1,3-butadiene when passed over aluminum oxide at 350° C.

The pyrolysis of cyclobutane apparently has not been recorded. Rozanov,[170] however, reported that methylcyclobutane is isomerized by contact with alumina at 350°-400° C. yielding a mixture of pentenes and their polymers.

Fillipov[171] observed the isomerization of methylenecyclobutane to methylcyclobutene in the presence of aluminum oxide at 300° C. At somewhat higher temperatures (395° to 430° C.) with this same catalyst, Dojarenko[172] found methylenecyclobutene to be converted into p-cymene, isoprene, hydrocarbons having the formula C_8H_{10}, and gaseous products.

Cyclopentane is the most stable of the cyclic saturated hydrocarbons, and its purely pyrolytic decomposition has not yet been reported. Some of its derivatives, however, have been dehydrogenated in the presence of substances known to be specifically dehydrogenating catalysts. For example, cyclohexylcyclopentane when passed at 300° C. over platinum deposited on charcoal yields phenylcyclopentane.[173]

CYCLOHEXANE

Jones[174] conducted an investigation on the thermal decompositions of cyclohexane, methylcyclohexane, and di- and tetra-hydronaphthalenes. The experiments were carried out in a glass bulb filled with broken porcelain and heated to 520° C. The decomposition of dihydronaphthalene began at 390° C. and that of the other three hydrocarbons started at 490° to 510° C. An analysis of the resulting gases showed the presence of large proportions of hydrogen, in contrast to the behavior of the higher paraffin hydrocarbons on pyrolysis. The gas from cyclohexane contained over 40 per cent of hydrogen and also olefins, benzene, methane, and ethane, the presence of the latter constituents indicating that, besides simple dehydrogenation, scission of a C—C bond had taken place. The liquid products from cyclohexane were found to contain benzene. The hydronaphthalenes decomposed with the production of much naphthalene, the gaseous products containing over 80 per cent of hydrogen. Jones concluded that the hydrocarbons studied tended, in general, to retain their ring structures.

Frolich, Simard and White,[175] investigating the formation of butadiene by the cracking of hydrocarbons, observed that at 654° C. cyclohexane yielded this diolefin to the extent of 20.6 per cent based on the cyclohexane decomposed. A calcium aluminate catalyst has been used for the decomposition of cyclohexane into ethylene and butadiene at 600° C.[176]

Ipatiev and Dowgelewitsch[177] studied the reactions of cyclohexane under the influence of heat with and without pressure and also in the presence of aluminum oxide, and found that this hydrocarbon is considerably more stable than hexane. At ordinary pressure and at a temperature of 750° C. the gaseous products from the decomposition contained hydrogen, 14.0 per cent; olefins, 44.5 per cent; and saturated hydrocarbons, 42.0 per cent. The liquid products contained unchanged cyclohexane, small amounts of olefins, and other hydrocarbons which did not react with a nitrating acid mixture nor with potassium permanganate. Under a pressure of 100 to 110 atmospheres the reaction was much more violent and at 510° C. the liquid products contained olefins (5 to 10 per cent), aromatic hydrocarbons, and cycloparaffins including methylcyclopentane. The isomerization of cyclohexane to methylcyclopentane took place under the influence of heat only at high pressure. In the presence of various catalysts, however, this isomerization takes place at ordinary pressure and at lower temperatures.

In the presence of silica gel, cyclohexane begins to decompose at 600° and cyclohexene at about 550° C., according to Mailhe.[178] The products indicated that cyclohexane is dehydrogenated to cyclohexene, which is subsequently converted to benzene and to hexene. Further degradation yields a series of olefins in which propylene predominates. Above 700° C. pyrolytic condensation to benzene, toluene, xylene, naphthalene, anthracene and more complex hydrocarbons occurs.

The dehydrogenation of cyclohexane in the presence of palladium black was found by Zelinsky and his collaborators[179] to be a reversible process. At 100° to 110° C. benzene was readily hydrogenated in its presence and the dehydrogenation of cyclohexane to benzene began at 170° C., attaining a maximum velocity at 300° C. Under similar conditions methylcyclohexane yielded toluene and hydrogen. Hexane, cyclopentane and methylcyclopentane were not affected so that this might constitute a method for isolating cyclopentane derivatives in the presence of cyclohexanes.

Nickel, palladium and platinum were found by Zelinsky to be dehydrogenating catalysts at temperatures of 150° C. to 408° C. Of these three, nickel was the poorest. Platinum and palladium black also appear in some cases to exhibit selective dehydrogenating action. Thus, when a mixture of cyclohexane and methylcyclohexane was passed over the catalyst, only the cyclohexane was converted to hydrogen and benzene while the methylcyclohexane remained unchanged. Other cyclohexane derivatives, hexahydrocymene and hexahydroxylene, were dehydrogenated by platinum black at 300° to 310° C. to yield the corresponding aromatic compounds, cymene and xylene. Zelinsky was of the opinion that in the dehydrogenation process all six hydrogen atoms were eliminated simultaneously, without the intermediate formation of either the di- or tetra-hydroaromatic compounds.

Methylenecyclohexane remained unaltered when heated with quinoline, but in the presence of a mixture of quinoline and quinoline hydriodide at 145° C., it was isomerized to 1-methylcyclohexene. The same change was brought about at 150° to 170° C. in the presence of benzoic acid.[180]

Cyclohexene when passed over palladium black at 92° C. yielded benzene and cyclohexane.[181] On heating in a bomb for 24 hours at 400° to 440° C. in the presence of aluminum oxide the products were hydrogen, gaseous saturated hydrocarbon bases, benzene and higher aromatic compounds.[182] 1,4-Dimethyl-3-cyclohexene at 140° C. in the presence of a palladium catalyst yielded principally dimethylcyclohexane. Toluene and methylcyclohexane were obtained from methylenecyclohexane at 116° to 118° C. in the presence of this same catalyst.[183]

The pyrolysis of allylcyclohexane, which has been studied by Hurd and

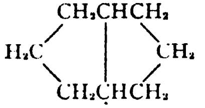
Bollman,[184] yields a predominating proportion of propylene and the liquid products consist of cyclohexane, benzene and cyclohexene, together with tars and high-boiling material.

CYCLOHEPTANE AND HIGHER CYCLOPARAFFINS

The purely thermal decomposition of cycloheptane has not been reported. Willstätter and Kametaka,[185] however, have shown that in the presence of nickel and hydrogen at 235° C. this hydrocarbon is converted to methylcyclohexane and dimethylcyclopentane. Under similar conditions, but at a temperature of 205° to 210° C., cyclooctane yielded dimethylcyclohexane together with some other hydrocarbons which were apparently alkylated cyclopentanes. Zelinsky and Freimann[186] reported that at 300° C. in the presence of a platinum catalyst cyclooctane is converted to methylcycloheptane and bicyclo-(0,3,3)-octane, the formula of which is



PYROLYSIS OF PETROLEUM DISTILLATES

The pyrolysis of petroleum distillates, principally from naphthene-base stocks has been reported by several investigators. Ogloblin[187] obtained benzene, toluene, naphthalene and other aromatic compounds by a two-stage process. In the first stage the naphtha distillate (from Russian petroleum) was passed through an iron retort heated to 525° to 550° C., and the product was obtained in three fractions: (1) gas, (2) liquid boiling below 200° C., and (3) liquid boiling above 200° C. The portion boiling below 200° C. was decomposed at temperatures of from 700° C. to 1200° C. under 2 atmospheres pressure. The product obtained by this second stage was fractionated and the fraction boiling up to 120° C. was called "gray benzol." This "gray benzol," amounting to about 12 per cent of the petroleum, contained benzene, toluene and xylene. Fraction 3 from the first stage, boiling above 200° C., can be used for the production of naphthalene, anthracene, and similar hydrocarbons.

The pyrolysis of naphthenic petroleum hydrocarbons has been reported by Engler and Rosner,[188] by Egloff, Twomey and Moore,[189] and by Leslie.[190] The most interesting feature of the experiments of Leslie was the production of large proportions of unsaturated compounds when a naphthene-base oil was thermally treated under conditions which bring about primary chemical change without extensive secondary reactions.

SUMMARY OF THERMAL REACTIONS OF NON-AROMATIC CYCLIC HYDROCARBONS

Far too little careful experimental work on the pyrolysis of the cycloparaffin hydrocarbons has been reported for any far-reaching generalization to be made concerning the mechanism of the process. Undoubtedly, however, cyclopentane and cyclohexane derivatives are the most stable, even more so than the corresponding paraffins. Cycloparaffins with less than 5 carbon atoms in their ring have a tendency to isomerize to the corresponding olefin when heated. The cyclohexanes tend to isomerize to the corresponding methylcyclopentanes under the influence of heat and pressure and this reaction can probably be effected at lower temperatures by certain catalysts, such as aluminum chloride. Hydrogen iodide has been also used to effect similar isomerizations of cycloheptane.

In the presence of catalysts such as nickel, platinum and palladium black, cyclohexane derivatives tend to dehydrogenate with the production of benzene derivatives but cyclopentanes resist dehydrogenation, according to Zelinsky. The indications are that cyclohexane derivatives undergo non-catalytic thermal decomposition at temperatures above 500° C. to yield aromatic hydrocarbons and hydrogen, but from cyclohexane itself Jones obtained a notable production of olefin and paraffin hydrocarbons of lower molecular weight. The mechanism of this latter process, which would appear to involve a scission of a C—C bond in the ring itself, is still very obscure and much more experimental work is needed to clarify it. In cycloparaffin derivatives containing one or more alkyl groups substituted for hydrogen atoms, it is reasonable to suppose that the paraffinic side-chains will react analogously to the paraffins but this supposition requires experimental verification. A very careful study of the non-catalytic thermal decomposition of cyclopentane and its derivatives would be extremely valuable.

Balandin[191] has developed a theory of dehydrogenation catalysis, based upon the same idea underlying the "space theory" of catalysis advanced by Langmuir, Adkins and Burk, of interest here. Catalytic dehydrogenation occurs, according to this theory, when a group of surface atoms appropriately spaced and of the necessary activity absorb the reactant in a definitely oriented position. Because simultaneous action on the part of several surface atoms is postulated the theory is called the "multiple-hypothesis." Catalysts such as platinum, palladium, iridium, rhodium, copper, cobalt, nickel, iron, zinc, osmium or ruthenium are active because they possess structures fulfilling this condition.

Other predictions made from this theory are:

(1) Cyclopentane and cycloheptane, containing 5- and 7-membered rings, respectively, should not be dehydrogenated by metallic catalysts.

(2) Cyclohexene and cyclohexadiene should not be obtained as partial catalytic dehydrogenation products of cyclohexane.

(3) Di-substituted cyclohexanes should not be dehydrogenated when the substituted groups are on the same carbon atom.

The calculations by Sachanen and Tilicheyev[192] of the equilibrium constants of a number of hydrocarbon reactions at 477° C. show that the naphthenes tend to be dehydrogenated to benzene derivatives and that side chains can split off with the formation of olefins. The naphthenes as a class are intermediate between paraffins and aromatics as regards their stability to heat.

THERMAL DECOMPOSITION OF AROMATIC HYDROCARBONS

Aromatic hydrocarbons as a class are more stable thermally than all other types of hydrocarbons and constitute the main product of the thermal decomposition of all other hydrocarbons at high temperatures. For example, aromatic hydrocarbons occur largely in the tar produced by the high-temperature carbonization of bituminous coal and also in the tar produced by the high-temperature cracking of liquid, solid, and gaseous hydrocarbons.

---

[191] *Z. phys. Chem., Abt. B*, 1929, **2**, 289; *Chem. Abs.*, 1929, **23**, 2872.

[192] *Loc. cit.*

The first important work on the pyrolysis of aromatic hydrocarbons was conducted by Berthelot,[193] who passed various hydrocarbons through a porcelain tube heated to dull redness. Under these conditions benzene gave diphenyl, chrysene, and a resinous substance but no anthracene or naphthalene. Toluene yielded benzene, naphthalene, anthracene, and other hydrocarbons. Xylene gave toluene as a principal product, also benzene, naphthalene, and anthracene. Cumene yielded toluene and xylene in large quantities as well as benzene, naphthalene, anthracene, and chrysene. Later, Anschütz [194] concluded that many of the complex hydrocarbons produced during pyrolysis are formed by condensation with elimination of hydrogen thus:

$$2C_7H_8 \longrightarrow C_{14}H_{10} + 3H_2.$$

Smith and Lewcock [195] studied the decomposition of benzene in an iron tube and found that the chief product was diphenyl and that the amount of product boiling above 260° C. was small. At 600° C. no diphenyl was formed and 800° C. was found too high for optimum yields. Up to 70 per cent yields of diphenyl were obtained and it was observed that the presence of easily reduced oxides or of coke in the reaction tube favored the production of diphenyl.

Rittman and his co-workers [196] studied the reactions of benzene, xylene, toluene, naphthalene, and anthracene at various temperatures and pressures. The xylenes gave toluene, benzene, naphthalene, and anthracene. Toluene yielded benzene, anthracene, and naphthalene. Benzene yielded only naphthalene and anthracene whereas naphthalene formed anthracene but no other aromatic compound. Later, Zanetti and Egloff [197] found that the chief product of the decomposition of benzene at temperatures of 500° to 800° C. were diphenyl, diphenylbenzenes, carbon, and permanent gas. The formation of diphenyl began at 500° C. and was at a maximum at 750° C. Contrary to the results of Rittman and his collaborators, no naphthalene was formed. The permanent gas consisted of hydrogen saturated with benzene vapor and no acetylene was present. The formation of diphenyl was not favored by any catalyst but the decomposition of benzene into carbon and hydrogen was accelerated by the presence of iron and nickel.

Dufton and Cobb [198] demonstrated that in a stream of nitrogen rich in benzene, decomposition begins at about 550° C., with the production of diphenyl. The yield of diphenyl increases with increasing temperature to a maximum but at more elevated temperatures further decomposition sets in and a three-ring compound, diphenylbenzene, is formed. Toluene at temperatures of 600° C. and above yielded ditolyl together with stilbene, naphthalene, anthracene, and other substances. Several other investigators have shown that diphenyl can be produced from benzene at temperatures between 500° and 1000° C., the optimum temperature being 750° C., and this material is now being produced on a large scale by thermal processes (see Chapter 4).

The pyrolytic decomposition of benzene, toluene, and xylene, heated separately in an atmosphere of hydrogen, at a temperature of 500° C., and at pressures up to 270 atmospheres has been reported by Oda.[199] Benzene was the most stable of

the three, yielding some methane and about 1 to 2 per cent diphenyl. Toluene was decomposed more readily, yielding benzene and a mixture of hydrocarbons which were probably derivatives of diphenyl. Xylene yielded benzene, toluene and a complex mixture of liquid and solid hydrocarbons, the solid ones appearing to be anthracene derivatives.

Hurd and Bollman[200] isolated naphthalene, toluene (and some benzene) together with propylene from the products of the pyrolysis of 4-phenyl-1-butene.

The work of Sachanen and Tilicheyev[201] on the decomposition of naphthalene and other aromatic hydrocarbons is of great interest. On heating naphthalene for 4 hours at 475° C. no carbon was formed and a dinaphthyl was isolated in the reaction products. Anthracene, heated to the same temperature for 2½ hours, yielded gaseous products and changed into a coke-like material, 60 per cent of which was insoluble in benzene.

Since fluorene[202] is produced by passing diphenylmethane through red-hot tubes, its presence in tars is probably due to similar pyrogenetic reactions. The production of styrene by passing a mixture of benzene and ethylene through red-hot tubes is another example of these thermal reactions.[203] By this method Berthelot[204] was able to produce acenaphthene from naphthalene and ethylene and phenanthrene from diphenyl and ethylene. The formation of picene (1,2,7,8-dibenzophenanthrene, found in the residues from the distillation of crude petroleum by Graebe and Walter[205]) and similar hydrocarbons deficient in hydrogen[206] can, no doubt, be attributed to pyrolytic reactions.

SUMMARY OF THERMAL DECOMPOSITION OF AROMATIC HYDROCARBONS

The aromatic hydrocarbons tend to decompose into benzene or its immediate homologues and these then undergo a characteristic reaction, two nuclei coalescing to form a substance of higher molecular weight and hydrogen being simultaneously liberated. Thus, benzene forms diphenyl and hydrogen by the latter process. The polynuclear aromatic hydrocarbons, such as naphthalene, may also condense similarly with loss of hydrogen. A repetition of this process many times suffices to give coke-like substances of low hydrogen content. In this way, aromatics are probably to be regarded as the principal source of coke and heavy residuum in cracking reactions. From pure hydrocarbons no tar or coke is formed at moderate cracking temperatures or with comparatively short times of cracking.

Sachanen and Tilicheyev have calculated the equilibrium constants of various hydrocarbon reactions at 477° C. from thermal data by the aid of the Nernst formula and have arrived at the following conclusions in regard to the pyrolysis of aromatic hydrocarbons. Of the substituted aromatic hydrocarbons, the methyl-substituted benzenes, and to a lesser extent the ethyl-substituted ones, are the more resistant to heat. On the other hand, the benzene homologues with longer side chains tend to decompose more readily, the result being a splitting off of the side chains with the formation of either olefins or paraffins. Of the latter reactions the formation of styrene proceeds most easily.

Some conclusions of Pease and Morton,[207] arrived at in a study of the kinetics of dissociation of typical hydrocarbon vapors, are of interest in a broad general way. At 600° C. the order of stability of the hydrocarbons investigated was o-xylene, toluene, benzene, m-xylene, ethylbenzene, cyclohexane, 2-pentene, ethylcyclohexane, n-heptane. The dissociations appear to be normal, first-order, homogeneous gas reactions. The higher members of a series dissociate somewhat more rapidly at lower temperatures than the lower members. A side-chain on the benzene ring has nearly the same properties as the paraffin of the same number of carbon atoms. The cyclohexane ring is less stable than the benzene ring. On reaction, it first probably yields a smaller cycloparaffin ring.

Chapter 3

Cracking Processes and Their Products

In the previous chapter the pyrolytic reactions of a number of individual hydrocarbons, representatives of certain chemical types, have been discussed and an attempt has been made to distinguish the various stages in the resulting complex series of reactions. In the present chapter a description will be given of the salient features of the commercial cracking processes which have for their main object the production of an optimum amount of high-grade motor fuel from the higher-boiling fractions of petroleum. In a discussion of this character it is not necessary to enter into great detail regarding the type of plant used or the operating conditions except in so far as they affect the yield and kind of products. From the viewpoint of the chemist, the greatest interest is centered around the gaseous and low-boiling liquid products of commercial cracking operations which, on account of their content of lower olefins and other reactive hydrocarbons, are rapidly becoming the raw materials of a great organic chemical industry. In particular the gaseous products of cracking, though heretofore regarded by the refiner as undesirable by-products of value only as gaseous fuels, are a potential source of very large quantities of the simple unsaturated hydrocarbons, especially ethylene and propylene, the ready availability of which is already exerting a tremendous influence on the development of industrial aliphatic syntheses.[1]

Industrial cracking operations are concerned almost exclusively with the conversion of petroleum oils of higher boiling range than gasoline into low-boiling liquids of the gasoline type. It is true that high temperature pyrolysis was utilized during the World War for the production of aromatic hydrocarbons from petroleum fractions and at the present time there are indications of developments in the pyrolysis of natural gases for the production of the lower olefins and of aromatic oils. Compared, however, with the extent and importance of the great cracking industry for the production of motor fuels from higher petroleum fractions, all other phases of pyrolysis are at the moment quite negligible from a commercial standpoint.

The development of the commercial cracking art has been phenomenal, especially during the last decade. Despite the continued overproduction of crude oil and the decreased production of straight-run gasoline and natural-gas gasoline in the United States, cracked gasoline production in this country increased from 394,000 barrels daily in 1929 to 432,000 barrels in 1930, and again in 1931 to 488,000 barrels.[1a] Besides greatly increasing the yield of gasoline obtainable from crude petroleum, the cracking operation is capable of furnishing gasolines of much better anti-knock value than straight-run products. With an increasing demand for gasoline of higher octane number the cracking process has become of paramount importance, and its flexibility has been so increased that not only kerosene, gas oil, fuel oil, and even crude oils are being cracked to motor fuel, but also straight-run gasoline, especially heavy naphtha, is being subjected to a certain degree of cracking to improve its anti-knock value.[1b] The figures in Table 24, which show the cracked gasoline production in the United States, expressed as percentages of the annual total gasoline produced in this country, clearly reveal the growth of the cracking industry.[2]

---

[1] See for example, Bowen, *Oil and Gas J.*, 1932, **30** (46), 88. Migey (*Refiner*, 1932, **11**, 547; *Brit. Chem. Abs.* B, 1933, 691) points out that cracking gas is an economical source of ethylene (98 per cent pure and sulphur free) which may be employed in the manufacture of metastyrene. Ellis (U. S. Patent 1,935,469, Nov. 14, 1933; assigned to Ellis-Foster Co.) suggests that after the removal of olefins the residual cracking gas be converted to hydrogen, which can then be used for catalytic hydrogenation operations. See also Egloff, *Ind. Eng. Chem.*, 1934, **26**, 41. The development of the oil cracking art is described by Keith and Montgomery, *Ind. Eng. Chem.*, 1934, **26**, 190.

TABLE 24.—*Percentage of Cracked Gasoline to Total Gasoline in the United States.*

Year	Per Cent	Year	Per Cent
1904	10.3	1923	31.0
1909	10.7	1924	33.0
1914	18.0	1925	34.9
1917	21.5	1926	37.7
1921	27.1	1927	40.0
1922	29.6	1928	41.0
		1930	43.0

Although the cracking of higher petroleum fractions for gasoline has been developed almost exclusively in the United States, a notable increase in cracking has taken place in certain other countries where the tariff position is such that crude oil can be profitably cracked after importation. This is particularly true of Italy.

Chemical Reactions Occurring during Cracking

The commercial cracking of petroleum hydrocarbons for gasoline is carried out at temperatures within the range of 400° to 650° C., and at atmospheric or higher pressures, depending upon the type of process employed. So-called vapor phase processes are operated at comparatively high temperatures and comparatively low pressures (usually atmospheric or slightly above atmospheric pressure), while those termed liquid phase processes necessitate the use of pressures up to 1000 pounds per square inch or higher in conjunction with a somewhat lower range of temperature, generally below 500° C. It is naturally impossible to set a definite temperature as the limit between liquid and vapor phase cracking operations, since this temperature will vary with conditions of pressure and also with the charging stock.[3] The hydrocarbon material to be cracked may be any petroleum fraction boiling above a medium gasoline range, though the gas oil fraction (the latter being the cut intermediate between the kerosene and lubricating oil fractions) is the usual cracking stock.[3a] In some instances "reduced" and "topped" crudes are used.[4] In the following discussion of the reactions involved in cracking operations attention is concentrated on the temperature range of 400° to 650° C., representing the limits of commercial operations at the present time.

[1b] Bataafsche Petroleum Maatschappij, French Patent 746,481, 1933; *Chem. Abs.*, 1933, **27**, 4665.

[2] Graetz, *Chim. et. ind.*, 1930, **24**, 271.

[3] The terms *liquid* and *vapor phase* were apparently used in early cracking developments to differentiate those processes operating at temperatures of about 400°-450° C. (750°-850° F.) and increased pressures from those employing higher temperatures, about 540° C. (1000° F.) and atmospheric or reduced pressures. Sometimes operations in which the charging stock passes into or through the cracking zone in the form of a mist or fog are erroneously designated vapor phase processes. In this connection compare Sachanen and Tilicheyev ("Chemistry and Technology of Cracking," The Chemical Catalog Co., Inc., 1932, 15), who, referring to McKee and Parker (*Ind. Eng. Chem.*, 1928, **20**, 1169), stated "it is entirely possible that these heavier components are also present in the state of an emulsion or as a fog, and that these non-homogeneous systems may be fairly stable."

[3a] From experiments on cracking Ragusa crude, Mariotti (*L'Ind. Chimica*, 1933, **8**, 4, 162; *Brit. Chem. Abs.* **B**, 1933, 338) concluded the best results were obtained with a fraction having a density of 0.91 to 0.92, and boiling between 186° and 360° C. Trusty (*Refiner*, 1932, **11**, 335; *Brit. Chem. Abs.* **B**, 1932, 968) considered the three criteria of a good cracking stock are: distillation range, carbon residue or tar number, and aniline point. An ideal cracking stock is a heavy closely fractionated gas oil, possessing a low carbon residue, and low aniline point.

The complete cracking process consists of a complex series of chemical reactions involving both decomposition and polymerization, the nature of the ultimate products being determined mainly by the character of the charging stock, the temperature and pressure of cracking and the time of exposure to cracking conditions.[5] Although a few of the primary cracking reactions exhibit a quasi-reversibility (for example, the dehydrogenation of paraffins to olefins and of cyclohexanes to benzene hydrocarbons and also, possibly, the polymerization and depolymerization of some olefins), most of the cracking reactions are of an irreversible character, the ultimate stable condition being in all probability the well-known methane-hydrogen-carbon equilibrium.

An insight can be gained into the various stages of the sequence of cracking reactions by the application of thermodynamics to the problem and also by a study of the primary cracking reactions of pure hydrocarbons. A knowledge of the free energy relationships of hydrocarbons enables us to predict whether a certain type of reaction is at all possible and also which of several competitive processes is the most likely to occur under any given conditions. On the other hand, thermodynamic calculations can tell us nothing of the rates at which reactions can proceed and, unfortunately, the transformations taking place in the cracking of petroleum are very largely controlled by the relative reaction rates. In order, therefore, to obtain a complete picture of such a complex sequence of processes it is necessary to consider not only the relative thermodynamic stabilities of various hydrocarbon types but also to correlate these with the results of experience in practical cracking operations and the experimental evidence obtained in the pyrolysis of pure hydrocarbons.

Thermodynamic Considerations

The thermodynamics of the thermal decomposition of various hydrocarbon types has been investigated theoretically by Francis and Kleinschmidt[6] on the basis of free energy calculations. Their results are best summarized by the graphs shown in Figure 12, in which the free energy per carbon atom of the formation of a number of hydrocarbons from their elements has been plotted against the temperature. Although, strictly speaking, one should compare the changes in free energy when starting with a definite weight of each of the two elements involved, a certain simplification is possible because of the fact that the carbon-hydrogen weight ratio is little different for various hydrocarbons over a considerable range. It will be seen from the curves that the free energies of formation (from their elements) of all hydrocarbons with the single exception of acetylene (and possibly the higher acetylenes) increase with rising temperature. Since the thermodynamic tendency at any temperature is from a higher to a lower line in the figure, it is obvious that all hydrocarbons tend to become increasingly unstable with respect to their elements with rising temperature, with the single exception of acetylene, which tends to become more stable at higher temperatures. It will be noticed also that the angles of slope of the curves for various hydrocarbons vary considerably and accordingly intersect one another. This indicates that the relative stabilities of different types of hydrocarbons are altered as the temperature rises. Thus, at temperatures below about 700° C. the ethylene curve lies above that of ethane, indicating that the tendency is towards hydrogenation in this lower range of temperatures, while at higher temperatures ethylene becomes more stable than ethane, i.e., the dehydrogenation reaction is favored. Because of the difference in the slope of the lines for the several olefin hydrocarbons they intersect at about 425° C., indicating that there is a tendency to polymerize below this temperature and to crack above this temperature. Other important conclusions which may be deduced from this series of curves can be summarized as follows:

---

[4] "Reduced crudes" refer to crude oils from which the gasoline, kerosene and some gas oil have been removed by distillation. "Topped crudes" are those from which gasoline or gasoline and kerosene fractions have been taken off.

Fig. 12.—Application of Thermodynamics to Chemical Reactions of Petroleum Products. (Francis and Kleinschmidt.)

(1) With the exception of methane and possibly ethane, all petroleum hydrocarbons are thermodynamically unstable at temperatures above about 200° C.

(2) No paraffin hydrocarbons can polymerize directly to higher hydrocarbons, and at cracking temperatures the paraffins are the least stable of all hydrocarbon types.

(3) The olefins are more resistant to heat than the paraffins and tend to polymerize below about 425° C. and to crack above that temperature. The iso-

merization of olefins to the corresponding cycloparaffins is a possible reaction at temperatures below about 425° C.

(4) The naphthenes are intermediate in their stability to heat between the paraffin and aromatic hydrocarbons. At higher temperatures the dehydrogenation of cyclohexanes to benzenoid hydrocarbons is favored, while the reverse change occurs in the presence of hydrogen at lower temperatures.

(5) The aromatic hydrocarbons, as a class, are most resistant to heat; particularly the large class of polynuclear aromatic materials, of which petroleum coke probably represents the limiting example.

The free energy calculations of Francis and Kleinschmidt lead to conclusions which are almost identical with those derived by Sachanen and Tilicheyev[7] from a calculation of the equilibrium constants of a large number of hydrocarbon reactions at 477° C. using the Nernst "approximation formula." Such thermodynamic considerations lead to the important conclusion, fully substantiated by experimental evidence, that most of the reactions occurring in practical cracking operations are of an irreversible character, in particular those involving the rupture of a C—C bond. Possible exceptions to this rule are the polymerization and depolymerization of monolefin hydrocarbons which exhibit a certain degree of reversibility. Depolymerization is complicated, however, by the occurrence of other reactions particularly at temperatures above 500° C. On the other hand, dehydrogenation and hydrogenation reactions of hydrocarbons are reversible under conditions within the somewhat narrow limits of stability of the hydrocarbons concerned.

ACTUAL STABILITY OF HYDROCARBONS[8]

Although the thermodynamic tendency for reactions to occur is determined by the free energy relationship existing under the conditions employed, experience has shown that in the cracking process the extent to which certain reactions proceed at the expense of other reactions is mainly dependent upon the *relative reaction velocities,* about which the laws of thermodynamics can tell us but little. In the range of temperature commonly used in commercial cracking operations of both liquid phase and vapor phase types, namely within the limits 400° to 650° C., experience indicates that the various series of hydrocarbons may be listed in the following order of decreasing tendency to crack (i.e., of increasing stability to thermal decomposition), the comparison being based on compounds of approximately the same molecular weights: (1) Paraffins; (2) monolefins; (3) diolefins; (4) naphthenes, mononuclear and polynuclear; (5) aromatics, mononuclear and polynuclear.[8a]

It should be emphasized that this purely qualitative classification of relative cracking tendencies is valid only within the temperature range 400° to 650° C., for at higher temperatures the diolefins become more stable than the naphthenes.

It has been further observed that the stability of the higher members of any given series increases with decreasing ratio of hydrogen to carbon in the molecule, i.e., the hydrocarbons most deficient in hydrogen are the most stable. An example of this rule is to be found in the polynuclear aromatic hydrocarbons. An exception to the rule is the higher naphthenes. In general, side chains in hydrocarbons have been found to be more stable to pyrolysis than the ends of straight chains.

---

[7] *Ber.,* 1929, **62**, 658.

[8] Frolich (*Chem. Met. Eng.*, 1931, **38**, 343) gave a review and description of the mechanism of cracking.

[8a] *Cf.* Pease and Morton, *J.A.C.S.*, 1933, **55**, 3190.

Some investigators reverse the order of the paraffins and monolefins. For example, Tilicheyev and Feigin[9] concluded from their results on cracking various hydrocarbons prepared synthetically or separated from petroleum fractions at 425° C. that the ethylenic hydrocarbons are more rapidly decomposed than paraffin hydrocarbons. This difference became small with increasing molecular weight. Thompson[10] reported that saturated branched-chain hydrocarbons are less stable than saturated straight-chain hydrocarbons, and that olefinic hydrocarbons decompose more readily than saturated hydrocarbons. The stability of olefinic hydrocarbons is greater the nearer the double linkage is to the center of the chain. McKee and Szayna[11] have followed the cracking of several gasoline fractions (boiling points 120° to 126° C.), and also of a number of hydrocarbons (aromatics, olefins and paraffins) at temperatures of 405° to 420° C. by determining the critical temperatures of the materials at definite time intervals. Olefin hydrocarbons appear to be the most rapidly decomposed, saturated hydrocarbons less rapidly, and the gasoline fractions decomposed slowest. The aromatics (a mixture of toluene and benzene) were apparently unchanged even after being heated for several hours.

PRIMARY AND SECONDARY REACTIONS IN CRACKING

In spite of the fact that, thermodynamically speaking, all liquid hydrocarbons are inherently unstable at temperatures above about 200° C., noticeable decomposition usually does not occur until temperatures of 300° C. or over are attained.[12] Even at these temperatures the reaction velocity is very slow. As may well be imagined, the temperature of initial decomposition varies markedly with different individual hydrocarbons, and for a complex mixture of hydrocarbons, such as a petroleum fraction, it depends principally upon the nature of the more unstable hydrocarbons present in the mixture, and also possibly upon the pressure. The velocity of cracking of petroleum fractions is generally far too small for practical purposes at temperatures below 400° C.

The complexity of the cracking process is attributable not only to the heterogeneous character of the hydrocarbon mixtures employed but also to the fact that each individual hydrocarbon on pyrolysis undergoes a sequence of cracking reactions, the nature and extent of which depend upon a large number of factors. It is obviously extremely difficult to investigate the reactions occurring during the cracking of such complex mixtures of hydrocarbons. A much clearer insight into the mechanism of the reactions concerned can be gained from an experimental study of the pyrolysis of pure hydrocarbons and from the thermodynamic considerations previously discussed. By this means it is possible to differentiate between the initial or *primary reaction products* and the secondary changes which occur on more prolonged cracking. The primary products invariably undergo a further sequence of secondary changes which tend to obscure the course of the reactions, particularly under prolonged treatment at cracking temperatures.

As previously stated, the paraffin hydrocarbons undergo pyrolysis more readily than other types of hydrocarbons. The initial cracking reaction of the paraffin hydrocarbons is either (1) a dehydrogenation of the paraffin with the production of an olefin of the same number of carbon atoms or (2) a rupture of a C—C bond with the formation of a lower paraffin and an olefin. The first reaction, noticeable with the lower paraffins, becomes less and less important as molecular weight increases and would appear to be quite unimportant under practical cracking conditions. In the second (the principal) primary reaction, the point of fission of the C—C bond appears to follow the law of chance, but it has been stated that the influence of pressure is to force the point of cleavage towards the center of the paraffin molecule with the production of a lower paraffin and an olefin, both of about the same molecular weight. According to some observers the most stable paraffins are those with 12 to 15 carbon atoms, but this needs more experimental confirmation. After the primary cracking reactions have taken place, secondary changes intervene by which the lower paraffin is further decomposed through the fission of a C—C bond and the olefins produced also undergo decomposition.

[12] Frolich, *loc. cit.*

The olefin hydrocarbons, which are rarely present in appreciable amounts in straight-run petroleum distillates and are to be regarded as the most important primary products of cracking, undergo decomposition in several ways. Polymerization reactions play an important rôle, particularly with olefins of higher molecular weights, and yield new compounds with molecular weights and boiling ranges higher than those of the original charging stock.[12a] Depolymerization can also occur with the formation of two olefins of lower molecular weight. And finally, simple cracking produces a diolefin and a paraffin hydrocarbon of lower molecular weight. The cyclicization of some of the monolefins to naphthenes is not improbable under cracking conditions.

The naphthene hydrocarbons may split and yield olefins at high temperatures (450° C. and above) and six-membered ring systems may be dehydrogenated to aromatic hydrocarbons. Naphthene hydrocarbons containing long side chains readily split off side chains at cracking temperatures.

The aromatic hydrocarbons, which are themselves formed from paraffin, olefin and naphthene hydrocarbons by a sequence of reactions at temperature of 550° C. and over, are very stable to heat, particularly the polynuclear members. They tend to form condensed ring systems in which the aromatic nuclei remain intact, hydrogen being simultaneously liberated. The aromatic hydrocarbons may be regarded as important coke-forming substances.[13]

Of the secondary changes taking place in the cracking of oils, polymerization of the olefins formed by the primary reactions is of very great importance. The high molecular weight material produced by such polymerization undergoes further cracking on prolonged exposure to high temperatures with the production of new unsaturated materials which can again undergo polymerization. The cumulative effect of this sequence of polymerizations and splitting reactions is the simultaneous formation of gaseous and low-boiling hydrocarbons, hydrogen, and more and more complex compounds of decreasing hydrogen content. Prolonged cracking invariably produces large amounts of petroleum coke which may be regarded as a highly polymerized hydrocarbon material of low hydrogen-carbon ratio. As previously pointed out, with decreasing hydrogen content the thermal stability and resistance to cracking increases markedly.

The above discussion refers to the cracking reactions predominating in the temperature range 400° to 600° C. At higher temperatures dehydrogenation reactions become very pronounced with greatly increased formation of aromatic hydrocarbons, much permanent gas, and coke.

[12a] The polymerized residues, after the removal of the lower-boiling constituents, may be employed, in conjunction with linseed oil, as a paint vehicle; Zilbermann, Jakubovitsch, Bolotin and Micheeva, *J. Chem. Ind. Russia*, 1933, No. 4, 16; *Chem. Abs.*, 1933, **27**, 5558.

PHYSICAL CHEMISTRY OF THE CRACKING PROCESS

A large number of workers have shown that the initial molecular breakdown of both pure saturated hydrocarbons and of petroleum fractions follows the law for homogeneous unimolecular reactions, and is therefore independent of the concentration.[14] Thus Geniesse and Reuter [15] studied the cracking of gas oil and of several naphthas at atmospheric pressure and showed that their results could be well expressed by the unimolecular equation

$$k = \frac{1}{t} \log_e \frac{a}{a - x}$$

where a = initial quantity of hydrocarbon; $a - x$ = quantity remaining at time t; k = reaction velocity coefficient.

This fits especially well at temperatures below 640° C. under conditions where the decomposition was not allowed to proceed too far. As the percentage decomposition increases the velocity constants decrease on account of the intervention of secondary reactions, such as polymerization, and the increasing thermal stability of the cracking stock through molecular rearrangement. Geniesse and Reuter found that the results of other workers on the pyrolysis of various pure hydrocarbons as well as their own observations of petroleum fractions can be represented by a family of curves of approximately equal slope (Fig. 13) indicating that the activation energies for the decomposition of all these hydrocarbons are about the same. In spite of the fact that Schneider and Frolich [16] have shown that reactions of the type

$$2C_3H_8 \longrightarrow C_2H_6 + C_4H_{10}$$
$$2C_3H_6 \longrightarrow C_2H_6 + C_4H_6$$

occur during the pyrolysis of a number of the simple paraffins and olefins, nevertheless these reactions, at first sight bimolecular, behave approximately as first order reactions.

Although all primary cracking reactions proper are thus approximately unimolecular, as soon as the secondary reactions become important (i.e., as the degree of decomposition is increased), the first order constant declines rather rapidly. This is to be ascribed partly to the occurrence of polymerization reactions since polymerization is a bimolecular process.[17] The velocity of polymerization reactions increases with rising temperature but much less rapidly than that of simple molecular decomposition.[18]

The heat effect of cracking is of considerable importance both from a practical and theoretical standpoint. The cracking process consists of a complex sequence of reactions, some of which are endothermic and some exothermic, so that the final heat effect depends on the character of the charging stock, the cracking temperature (which influences to some extent the type of cracking reactions predominating), and the degree of cracking. In general, purely cracking reactions such as the splitting of a C—C bond, and dehydrogenation reactions, such as the dehydrogenation of cyclohexane to benzene and of ethane to ethylene, are highly endothermic. On the other hand, polymerization reactions are usually exothermic. Frey and Hepp [19] have shown that during the pyrolysis of the lower paraffins to produce aromatic hydrocarbons the rapid initial highly endothermic reaction producing olefins (accompanied by a heat absorption of about 450 calories per gram) is followed by a slower aromatization reaction which is exothermic to the extent of about 190 calories per gram. Evidently, therefore, the conversion of olefins into aromatic hydrocarbons occurs as a series of changes, the overall heat effect of which is decidedly exothermic.

FIG. 13.—Variations of Reaction Velocity Constant with Temperature. (Geniesse and Reuter.)

In practical cracking operations for the production of gasoline, however, endothermic reactions greatly predominate over exothermic reactions and the total heat effect is a negative one, being of the order of 500 calories per gram of gasoline formed.[20] For reasons already stated, the reader will rightly con-

---

[20] Obryadchikov, *Repts. Conf. on Cracking Hydrogenation Grozny*, 1931, 1, 67; *Chem. Abs.*, 1932, 26, 1104.

The amount of heat absorbed during the cracking reaction per meter of tube (linear velocity of material through the tube being 1 meter per second) is expressed by the equation

$$Q \text{ reac.} = \frac{500 G_2 P_{400}\, 2^{\frac{t_{400}}{10}}}{100}$$

in which G_2 is the weight of the stock through the tube, P_{400} the percentage of cracked gasoline formed at 400° C., and t is the temperature of the liquid in this section of the tube (Obryadchikov, *Neft. Khoz.*, 1929, 16, 357; *Chem. Abs.*, 1929, 23, 4808).

In some instances, however, a figure of 250 calories per gram of 374° F. end point gasoline formed is used as the net total heat effect of cracking.

clude that the heat effect of cracking is a variable figure depending upon a number of factors.

FUNDAMENTAL FACTORS INFLUENCING CRACKING

Of the various factors influencing the extent and character of the thermal reactions of hydrocarbons the most important are temperature, duration of heating, pressure, character of heating surface or presence of catalytic materials, and the nature of the hydrocarbons undergoing pyrolysis.[20a] The following is a brief discussion of the effect of each of these factors, with special reference to commercial cracking operations.

Temperature. Temperature not only influences the type of cracking reactions which occur but also exerts a striking influence on the reaction velocity. Cracking of liquid petroleum hydrocarbons may begin at temperatures as low as 200° C., depending upon the character of the more unstable hydrocarbons present, but it is not sufficiently rapid for technical purposes until temperatures above 400° C. are attained. On the other hand Ryonosuke Abe[21] concluded, from the heating curves of petroleum oils taken at atmospheric pressure, that a temperature of 300° C. is necessary before cracking became fairly rapid. The velocity of cracking, although closely dependent upon the temperature, varies somewhat at any particular temperature for different types of oils.

As previously noted, the initial cracking reaction has been shown to be approximately unimolecular, and the velocity constant k can be represented by the equation

$$k = \frac{l}{t} \log_e \frac{a}{a - x}$$

Certain approximations become necessary in applying this formula to petroleum distillates, since the quantity of unchanged material cannot be readily determined. Geniesse and Reuter[22] have successfully applied it to the cracking of a Mid-Continent gas oil at atmospheric pressure by taking as unchanged material $(a - x)$ all the oil in the product after removal by distillation of the gas, gasoline, and higher-boiling products, i.e., all material boiling outside the range of the original fraction. The effect of temperature upon the velocity constants so obtained with the gas oil examined by Geniesse and Reuter could be represented by the formula

$$k = 28.8\, e^{-53{,}400/RT}$$

For this the activation energy is 53,400 calories per gram molecule. Data for a number of other pure hydrocarbons indicated that the activation energies of the cracking reaction are approximately the same except for hydrocarbons, such as ethylene, undergoing bimolecular polymerization reactions. Unfortunately for the above mode of computation, the unimolecular reaction constants tend to decline as the cracking proceeds because of secondary changes which are not of the first order.

It has repeatedly been stated[23] that the velocity of cracking is doubled for every 10° C. rise in temperature, but this is probably only a very rough approximation and the actual value appears to change somewhat less rapidly with the temperature of cracking. The experiments of Geniesse and Reuter indicated that the reaction rate of cracking a Mid-Continent gas oil at 1 atmosphere (and hence in the vapor phase) doubled for an increment of 14° C. at 450° C. and for an increment of 21° C. at 600° C. Leslie and Potthoff[24] reported that in the formation of gasoline from gas oil and heavy oil the yield doubled for every rise of 12° C.

[20a] The fundamental variables in mixed-phase cracking (time, temperature and pressure) and their effects on the yields and characteristics of the products are discussed by Sydnor, *Ind. Eng. Chem.*, 1934, **26**, 184.

[21] *J.S.C.I.* (*Japan*), 1929, **32**, 152; *Chem. Abs.*, 1929, **23**, 5035. Waterman and te Nuyl (*Petroleum Z.*, 1931, **27**, 539; *Chem. Abs.*, 1931, **25**, 5976) report that with heavy distillates (vaseline oil) cracking was slight at 500° C. and became pronounced at temperatures of about 600° C.

[22] *Ind. Eng. Chem.*, 1932, **24**, 219.

[23] For example, Singer, *Petroleum Z.*, 1929, **25**, 893; 1930, **26**, 482. Humphreys, Rogers, and Paulus, U. S. Patent 1,553,861, Sept. 15, 1925; assigned to Standard Oil Co. of Indiana; *Chem. Abs.*, 1925, **19**, 3585.

At any one temperature the actual velocity of cracking depends definitely on the character of the charging stock. An investigation of this factor has been carried out by Sachanen and Tilicheyev[25] who studied the cracking of fractions of narrow boiling ranges, chiefly of Grozny oil, in a small shell still at final pressure of 61 to 100 atmospheres. At one particular temperature the rate of cracking was lowest for the lightest fractions and gradually increased for the heavier components. For example, under the same conditions of cracking a gasoline fraction (boiling 180° to 220° C., specific gravity 0.793) yielded 12 per cent of cracked gasoline (boiling up to 180° C., specific gravity 0.728) and an engine oil (boiling 250° to 280° C., specific gravity 0.910) gave 22.4 per cent of cracked gasoline (boiling up to 200° C., specific gravity 0.735).

In agreement with the conclusion that in the cracking process there is a progressive tendency for the production of hydrocarbons of increasing thermal stability, Sachanen and Tilicheyev found that cracked oils decompose at considerably slower rates than straight-run oils of comparable boiling range. Leslie and Potthoff observed that cracked residuum is decomposed at 427° C. at about half the velocity at which heavy fuel oil cracks. On the other hand, Geniesse and Reuter reported that pressure-cracked naphthas crack more easily than straight-run crude naphthas.

FIG. 14.—Degree of Cracking as a Function of Time of Contact. (Frolich.)

Duration of Cracking. As the time of contact of the hydrocarbons in the cracking zone is prolonged the primary cracking products undergo a series of secondary changes, the final result of which is to produce more and more fixed gas and coke. The formation of coke does not occur in the first stages of the cracking process and only begins when products of condensation (i.e., polymerized oils) in the form of high specific gravity oil have been produced. The velocity of coke formation increases with increasing time of cracking. The change of composition of the cracked products with increasing time of contact is shown graphically in a qualitative way in Figure 14.[26]

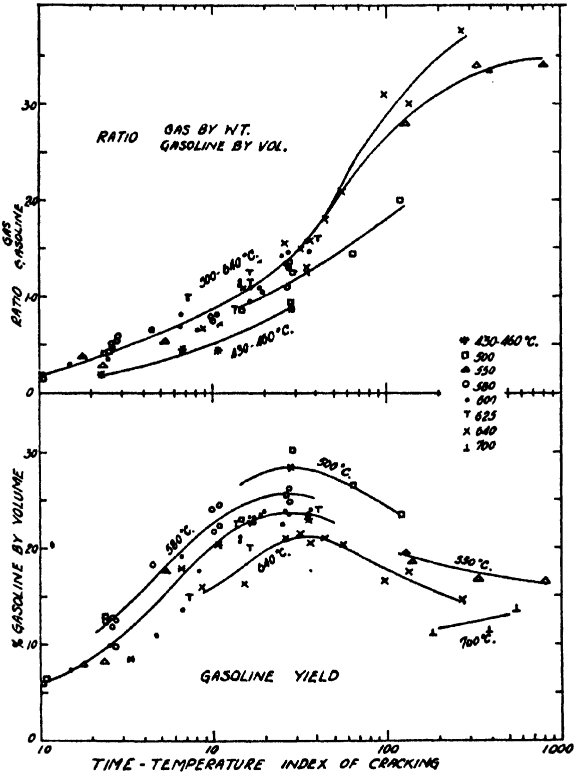
[24] *Ind. Eng. Chem.*, 1926, **18**, 776.

[25] *J. Inst. Pet. Tech.*, 1928, **14**, 761; *Petroleum*, 1927, **23**, 521.

[26] Strout, *Refiner*, 1929, **8**, 64; *Am. Pet. Inst. Proc. 10th Ann. Meeting*, 1930, 11 (1), Sect. III, 46; *Chem. Abs.*, 1930, **24**, 1965.

It has been shown by a large number of workers that prolongation of the cracking period has the same influence on the yield of products as an increase in the temperature of cracking, i.e., the results obtained at high temperatures and short times of contact can be duplicated approximately by using longer times of contact at lower temperatures. The validity of this rule, which is to be regarded as an approximation only, is restricted to the temperature range of commercial cracking reactions, i.e., 400° to 650° C. Geniesse and Reuter[27] found it convenient to consider the time and temperature factors together as a time-temperature index. Taking 480° C. as a standard temperature condition and assuming that the velocity of cracking is doubled for a rise of temperature of 17° C., this time-temperature index may be expressed as,



Courtesy Industrial and Engineering Chemistry.

FIG. 15.—Time-Temperature Index of Cracking of a Mid-Continent Gas Oil. (Geniesse and Reuter.)

$$\left(2^{\frac{T-480}{17}}\right) \times t$$

where T = cracking temperature in ° C.; and t = time of contact in minutes.

---

[27] Ind. Eng. Chem., 1930, 22, 1274.

The influence of varying the time-temperature index on the yields of gasoline and on the ratio of gas to gasoline obtained in the cracking of a representative Mid-Continent gas oil at temperatures of 430° to 700° C. and at atmospheric pressure are shown in the appended series of curves (Fig. 15) by Geniesse and Reuter. In plotting these curves the logarithm of the time-temperature index was employed rather than its numerical value. From the curves it is seen that as this index increases the yield of gasoline increases rapidly until a maximum value is reached. From then on the yield decreases slowly as the index increases. The curves also indicate that for a given value of the time-temperature index the yield of gasoline is higher at the lower cracking temperatures. The ratio of gas to gasoline continuously increases with the time-temperature index, becoming very large for values of the index greater than that corresponding to the maximum yield of gasoline.

The parallel influence of time of contact and temperature on the degree of reaction is not restricted to the cracking of petroleum fractions for gasoline production but appears to be a general phenomenon in the pyrolysis of all hydrocarbons. For example, Frey and Hepp[28] showed that in the pyrolysis of gaseous paraffin hydrocarbons at high temperatures to yield aromatic liquids, variation in time or in temperature gave equivalent results with respect to the yield of volatile oils over a wide temperature range. It was found that the minimum values of contact time required to develop an approximate maximum yield of volatile oils at any particular temperature was related to that temperature by the empirical formula:

$$T = 691 - 100 \log t$$

where T = temperature; and t = time in minutes.

The influence of the time factor on the yields of gasoline from the cracking process is that gasoline production becomes slower and slower as cracking is prolonged and the total gasoline yield tends to approach a limit. Recycling experiments carried out by Sachanen and Tilicheyev, with a charging stock of light gas oil in a small shell still operating under pressure, showed that the gasoline yield was 17.5 per cent in the first pass, and increased to 55 per cent after four passes. After repeated runs the yield of gasoline seemed to approach a limit of about 60 per cent with moderate coke formation or 65 per cent with considerable coke production.[28a]

Pressure. In the temperature range (400° to 650° C.) normally used in liquid phase processes the more volatile hydrocarbons are above their critical temperatures and only the less volatile ones are in the liquid condition under pressure. With increasing pressures the more volatile hydrocarbons are dissolved to a greater degree in the liquefied heavy ends so that only at very high pressures is a true liquid phase (or homogeneous) system obtainable. Moreover, it is doubtful whether there is such a thing as a liquid phase process in the usual sense of the word. Operating conditions which would constitute a liquid phase for the charging stock will not continue to exist as the structure of the hydrocarbon molecules is broken down to form lower boiling fractions. With increasing conversion to lighter hydrocarbons (secured by increasing the time factor under constant temperature conditions) the ratio of vapor to liquid increases so that such processes obviously operate as a heterogeneous gas-liquid system. The influence of pressure on the character of the cracked products is closely dependent upon the degree to which solution of the cracked products in the liquefied oils takes place.

---

[28] *Ind. Eng. Chem.*, 1932, **24**, 282.

[28a] This decrease in gasoline formation on recycling was also observed by Tarasov and Seledzhiev, *Neft. Khoz.*, 1932, **23**, 177; *Chem. Abs.*, 1933, **27**, 2022.

The great technical advantages of the use of higher pressures are that the best conditions for heat transfer, absence of local superheating and economy of fuel are thereby attained. The influence of pressure on the velocity of cracking has been the subject of a number of somewhat contradictory statements. It seems, however, that pressure exerts little influence on the velocity of cracking in the initial stages when the temperature and time of reaction are maintained constant. As cracking reactions proceed, however, the yield of gasoline undergoes a slight decrease probably because of polymerization of the unsaturated hydrocarbons into high-boiling compounds.[29] The apparent increase in the velocity of cracking with increased pressure is probably to be accounted for by the increased time of contact as a result of continued separation of material from the vapor phase to the liquid state and to the better heat transfer thus obtained.

From a theoretical standpoint there is no reason to suppose that increased pressure will favor the primary cracking reactions except by facilitating heat transfer. On the basis of Le Chatelier's theorem increased pressure should suppress the formation of uncondensible gaseous products. However, pressure undoubtedly plays a very important part in determining the course of the secondary changes in cracking operations. Since polymerization (of olefins) is a bimolecular reaction, the rate of which is proportional to the square of the pressure, it is to be expected that the use of high pressures will favor the polymerization of the unsaturated hydrocarbons initially formed in the first stages of the process, a phenomenon which has been repeatedly observed in the case of individual olefins. This is in accord with the observations made by numerous investigators that an increase in the pressure reduces the unsaturated hydrocarbon content of the resulting cracked gasoline.[30] Sachanen and Tilicheyev[31] found, for example, that when paraffin wax (melting point 53° C.) was cracked under 10 atmospheres pressure the gasoline produced had an iodine number of 107.8. When cracking was carried on under 40 atmospheres pressure the iodine number of the gasoline was 58.8. These figures indicate a decrease in the content of unsaturated hydrocarbons in the cracked gasoline by about one-half. Philippide[31a] noted when kerosene was cracked at 600° C. in an electrically heated tube that increasing the pressure from 1 to 20 atmospheres resulted in a decrease in the percentage of unsaturated hydrocarbons in the product.

This decrease in the proportion of unsaturated hydrocarbons at higher pressures is accompanied by the formation of polymerization products and of naphthenes. According to Frolich,[32] however, the favorable influence of pressure in promoting polymerization reactions is gradually counterbalanced by the increasing segregation of the olefins of high and medium molecular weight (which are the ones most readily polymerized) with rising pressure into the liquid phase where, by dilution with cracking stock, their rates of polymerization are slowed down considerably. The net result of this forcing by pressure of the vaporized olefins into the liquid phase is that polymerization and coke formation under certain conditions at first increase very rapidly with rising pressure, gradually increase more slowly, then pass through a maximum and at higher pressures coke formation actually declines.

In addition to its influence in depressing the content of unsaturated hydrocarbons in cracked benzines (already noted), increase of pressure also decreases the yields of gasoline obtained under a given combination of conditions particularly with intensive cracking when secondary changes become important. The use of increased pressures will tend to suppress gas formation in cracking, especially in dehydrogenation reactions in which the rate of dehydrogenation is retarded by raising the pressure.

---

[29] Sachanen and Tilicheyev, *Oil and Gas J.*, 1929, **28**, 48. Kato (*J. Soc. Chem. Ind. Japan*, 1933, **36**, suppl. binding 226; *Chem. Abs.*, 1933, **27**, 3808) reports that both the cracking rate and yield of gasoline decrease with increase of pressure through the pressure range of 60 to 300 atmospheres.

[30] E.g., Singer, *Petroleum Z.*, 1929, **25**, 893; 1930, **26**, 482.

[31] *Ber.*, 1929, **62**, 658.

[31a] *Petroleum Z.*, 1932, **28** (51), 1; *Chem. Abs.*, 1933, **27**, 1493. See also Kato, *J. Soc. Chem. Ind. Japan*, 1932, **36**, suppl. binding 226; *Chem. Abs.*, 1933, **27**, 3808.

[32] *Chem. Met. Eng.*, 1931, **38**, 343.

In view of the fact that coke formation is mainly dependent upon polymerization and recracking reactions producing high boiling asphaltic residuum oils (which are to be regarded as the parent substances of coke), it is to be expected that pressure will exert some influence on coke formation. As previously noted, the development of coke, like polymerization reactions, increases with rising pressure, rapidly at first, and then more slowly until it ultimately passes through a maximum and then declines. This is explained on the basis of the slowing down of polymerization velocity as the higher olefins are forced by increasing pressure into solution in the liquid phase and consequently diluted. Frolich[33] stated that polymerization and recracking reactions, the precursors of coke formation, are greatly depressed at ordinary cracking temperatures under 600 to 1000 pounds pressure as compared with, say, 100 to 200 pounds pressure. On the other hand, Graetz[34] found that, contrary to general belief, the formation of coke appears to be independent of the pressure applied. In any case, the pressure factor is of less importance in coke formation than temperature, duration of heating, and character of the charging stock.

CATALYSTS IN CRACKING

The thermal reactions of hydrocarbons are greatly influenced by the presence of certain catalytic materials in the reaction zone. Catalysts tend to promote the rapid attainment of an equilibrium condition at any particular temperature but, where a large number of intermediate stages are possible as in the thermal reactions of hydrocarbons, selective catalysis may occur and one reaction may be accelerated by one particular contact material.

The fundamental equilibrium to which all systems of hydrocarbons tend to revert at temperatures above about 500° C. is the methane-hydrogen-carbon equilibrium represented by

$$C + 2H_2 \rightleftharpoons CH_4$$

The attainment of this equilibrium takes a considerable time even in the presence of active catalysts and in the absence of catalysts it is approached only at high temperatures.

An investigation of the catalytic effect of a number of substances on thermal decomposition of methane was made by Slater.[35] He concluded that the chemical nature of the catalyst, as well as the area of the surface exposed, is of great importance.

The researches of Schützenberger and Jonine,[36] Zelinsky,[37] Mayer and Altmayer,[38] Slater,[39] Cantelo,[40] Zanetti,[41] and a large number of other workers have shown that the elements of the VIIIth Group, iron, nickel, and cobalt, are very active catalysts in promoting the decomposition of hydrocarbons into carbon, hydrogen, and methane. It is possible that this reaction is affected by the intermediate formation of metallic carbides. On treating the products of carbonization taken from the wall of an iron tube used in the pyrolysis of petroleum at 650° C. with dilute mineral acid, Zelinsky obtained a gas of the composition methane 12 per cent, hydrogen 85 per cent, and unsaturated hydrocarbons (C_nH_{2n}) 2.2 per cent, and an analysis of the original material showed 30 per cent iron and 70 per cent carbon. Scheffer, Dokkum and Al[42] found evidence of the formation of an unstable nickel carbide at comparatively low temperatures during the decomposition of methane in the presence of that metal.

Numerous statements have been made that the production of gasoline or of aromatic hydrocarbons may be promoted by the presence of various catalysts but none of these catalysts, with the exception of aluminum chloride and iron oxide, are used industrially to any extent. Thus Ostromislensky and Burshanadse[43] reported that by using a spiral of iron gauze in the pyrolysis of naphtha at 700° C. the yield of benzene obtained was increased from 7.75 per cent to 10.9 per cent, and that asbestos, pumice, iron oxide and carbon promoted the formation of hydrogen and carbon. Zelinsky proposed the use of zinc oxide for increasing the yield of aromatic hydrocarbons by high temperature cracking but doubt has been thrown on the utility of the substance by the work of Bjerregaard.[44] According to Snelling,[45] colloidal graphite considerably reduces the pressure necessary for the liquid phase cracking of naphtha to produce benzine. Later, Chamberlin and Bloom[46] observed that the carbon first formed exerts a catalytic effect on the formation of aromatic hydrocarbons in the pyrolysis of natural gas and similar results were reported by Fischer and Pichler[47] in the thermal polymerization of acetylene.

The use of activated aluminum as a catalyst with chlorinated petroleum hydrocarbons has been suggested.[48] The petroleum fraction is first chlorinated until a 65 per cent increase in weight occurs. The chlorinated petroleum, either alone or admixed with some of the original fraction, is then passed over activated aluminum at temperatures of 150 to 250° C. The aluminum is activated by treatment with the solution of a less electro-positive metal, which is thus deposited on the aluminum. This cracking process apparently involves the elimination of hydrogen chloride from the chlorinated petroleum, followed by thermal decomposition of the olefinic hydrocarbons thus formed.

A number of investigators agree that silica, porcelain, and siliceous materials are not active catalysts for the decomposition of the gaseous paraffins into their elements. Similarly copper and tungsten have little effect on the decomposition of hydrocarbons into carbon and hydrogen.[49] Copper tubes have been used by Chamberlin and Bloom[49] and by Wheeler and Wood[50] for the production of aromatic hydrocarbons by the high temperature pyrolysis of gaseous paraffin hydrocarbons. Iron and nickel, on the other hand, are active catalysts of the formation of carbon and hydrogen from methane. The carbon, resulting from the pyrolysis of natural gas, exhibits a selective activity in the conversion of paraffins to aromatics. With the lower molecular weight hydrocarbons decomposition seems to take place through intermediate formation of labile residues,[51] while, as previously mentioned, the higher molecular weight compounds split yielding one saturated and one unsaturated molecule as the primary reaction.

The action of aluminum chloride, which promotes the cracking of hydrocarbons even at low temperatures, is unique and warrants a chapter to itself (see Chapter 6).

With the exceptions of aluminum chloride and of iron, none of these substances is used for the production of gasoline by commercial cracking. Most cracking tubes are made of iron but their surfaces rapidly become covered with a deposit of carbonaceous materials which inhibits any catalytic activity the metal might exert. Among the catalytic cracking processes must also be classed those in which a mixture of oil and steam is subjected to decomposition in the presence of catalysts such as iron, nickel, or aluminum. In the Ramage process, for example, a mixture of hydrocarbon vapor and steam is led over a reducible metal oxide such as iron oxide.[52]

Although it has been repeatedly stated that certain specific catalysts are advantageous in promoting gasoline production and in simultaneously suppressing coke formation, the use of such catalysts in commercial cracking operations has been almost negligible.[53] It has been proposed, for example, to employ molten catalysts such as alkali metal cyanides, certain alloys, and other metallic catalysts.[53a] A large number of solid contact catalysts have been suggested as applicable in both the liquid and vapor phases, including difficultly reducible metallic oxides, certain metallic metaphosphates, activated carbonaceous materials, complex carbides such as iron-tungsten carbide, and elemental silicon. Volatile catalysts for vapor phase operation include mercury vapor and the halogens. Oil-soluble metallic acetylacetonates, particularly of the elements contained in Groups III to VII of the Periodic System, have been proposed as catalysts for liquid phase cracking.[54]

INFLUENCE OF THE CHARACTER OF THE CHARGING STOCK

The character of the charging stock is of much greater importance in influencing the yields of products of liquid phase cracking (i.e., under pressure below 500° C.) than in cracking at higher temperatures in the true vapor phase.

[51] Bone and Coward, *J.C.S.*, 1908, **93**, 1197. For a discussion of the mechanism of the pyrolytic decomposition of paraffin hydrocarbons see also Chapters 2 and 4.

[52] U. S. Patent 1,687,890, Oct. 16, 1928; assigned to Gyro Process Corp. See also U. S. Patents 1,403,194, Jan. 10, 1922; 1,409,404, Mar. 14, 1922; 1,752,692, Apr. 1, 1930; and British Patents 338,904 and 338,905, 1929.

[53] For a review of a number of such patents, see Egloff, Lowry and Schaad, *J. Inst. Pet. Tech.*, 1930, **16**, 133-246.

[53a] Ivanyss (*Petroleum Z.*, 1933, **29** (20), 1; *Brit. Chem. Abs.* **B**, 1933, 612) employed iron, tin, aluminum and nickel together with some chlorides, e.g., calcium, magnesium zinc or ferric chloride. Aluminum chloride was found to be a better catalyst than any of the metals. Titanium, tantalum or tantalum alloys have also been suggested (Mittasch, Stern and Galle, U. S. Patent 1,922,491, Aug. 15, 1933; assigned to I. G. Farbenindustrie A.-G.; *Chem. Abs.*, 1933, **27**, 5181) as well as steel alloys containing 5 to 8 per cent of chromium and small amounts of aluminum, silicon, molybdenum, vanadium, titanium, beryllium or copper (Vereingte Stahlwerke A.-G., British Patents 382,355 and 384,016, 1932; *Chem. Abs.*, 1933, **27**, 4387). Ansolvo acids have been proposed also (Galle, Rosinsky and Hofmann, U. S. Patent 1,923,571, Aug. 22, 1933; *Chem. Abs.*, 1933, **27**, 5181). Ugarte (French Patent 665,604, 1928; *Chem. Abs.*, 1930, **24**, 954; Australian Patent 18,020, 1929; *Chem. Abs.*, 1930, **24**, 3897) cracked heavy hydrocarbons by mixing them with basic, acid or neutral nitrates and subjecting the mixture to a temperature not exceeding 390° C. Another method is passing the hydrocarbons through a bath of a molten metal in which silicon carbide is the catalyst (Seelig, German Patent 546,124, 1929; *Chem. Abs.*, 1932, **26**, 3369; German Patent 573,455, 1931; *Chem. Abs.*, 1933, **27**, 3068).

For descriptions of apparatus in which catalysts are employed, see Sinclair Refining Co., German Patent 475,836, 1925; *Chem. Abs.*, 1929, **23**, 3804; and German Patent 497,428, 1926; *Chem. Abs.*, 1930, **24**, 3637; Seigle, U. S. Patent 1,913,061, June 6, 1933; *Chem. Abs.*, 1933, **27**, 4378; I. G. Farbenindustrie A.-G., French Patent 681,404, 1929; *Chem. Abs.*, 1930, **24**, 4385.

[54] I. G. Farbenindustrie A.-G., British Patent 337,046, 1929; *Brit. Chem. Abs.* **B**, 1931, 54.

In the latter, variations in the character of the charging stock exert but little influence on the yield and nature of the products, particularly gas, gasoline, and tar, under comparable conditions.[55]

In a discussion of the influence of the charging stock on cracking operations it is necessary to repeat many of the items previously mentioned. Such a repetition, however, will serve as a brief summary of the fundamental features of cracking.

In low-temperature cracking the character of the charging stock greatly influences, first, the velocity of cracking. On the basis of hydrocarbons of approximately equal molecular weights, the relative ease of cracking of the various series is in the order: paraffins, naphthenes, and aromatics (most difficult). Again, at a given temperature the higher boiling petroleum fractions crack more rapidly than do the lower fractions, and cracked products undergo re-cracking much more slowly than the original materials. Second, other factors being the same, it may be expected that the type of charging stock will influence the chemical composition of the gasoline produced. For example, a highly naphthenic distillate might be expected to yield a gasoline containing an abnormally large proportion of naphthenic and aromatic hydrocarbons. The constitution of the gasoline depends also to a large degree upon other factors, the most important of which are the temperature and duration of heating. Third, experience has shown that the yield of gasoline from different charging stocks (high-boiling petroleum distillates and heavy crude oils) varies somewhat with oils from different sources. Fourth, the rate of coke-formation, according to Singer,[56] depends upon the chemical composition of the charging stock, paraffinic stocks producing less coke than paraffin-free or asphaltic oils under similar conditions of cracking. He stated that kerosene yields practically no coke, solar and spindle oils, very little, and machine and cylinder oils, large quantities, while tars greatly increase the formation of coke. The yield of coke appears to be of greater importance in determining the details of a cracking operation than are the yields of cracked gasoline (which are the same for a given temperature and cracking time from heavy crude oils and mazout).[57]

As already noted, oils containing a relatively large proportion of higher aromatic hydrocarbons tend to form larger quantities of coke.

COMMERCIAL CRACKING PROCESSES

As has been mentioned previously, it is neither necessary nor desirable to enter into a detailed description of the various types of cracking plants now employed for the production of motor fuels from higher-boiling petroleum fractions or from topped or reduced crudes. The technical literature on the subject is voluminous and the number of processes is great and increasing rapidly.[58] To the petroleum chemist interested in the manufacture of organic chemicals, the principal interest in cracking is associated with the by-products of the process, and particularly with the gaseous by-products, which are valuable sources of large quantities of the lower olefins. In the following brief description of commercial cracking special attention is given to modern tendencies in vapor and liquid phase cracking operations.

Pet. News*, 1930, **22** (3), 30.

Liquid Phase Processes. One of the first important developments in liquid phase cracking for gasoline production was that of Burton, subsequently improved by Clark. In this process gasoline was formed by a simple pressure distillation (under about 5 atmospheres pressure) in a steel shell supplied with tubes as heating surfaces. Thus, on heating 200 barrels of gas oil, or similar distillate, in a Burton still of 250 barrels capacity, under a pressure of 75 to 80 pounds per square inch, cracking began at about 340° C. Slow distillation for a period of 40 to 45 hours with a gradual rise in temperature to about 430° C. yielded a pressure distillate equivalent to about 60 to 65 per cent of the volume of the charging stock and about one-half of this pressure distillate was obtained as gasoline of 440° F. end point ("unsaturation" to sulphuric acid, about 10 to 12 per cent). The overall yield of gasoline was therefore of the order of 30 per cent. The method of pressure distillation employed in the Burton process possessed the disadvantages of very low capacity and undue coke-formation through local overheating. For this reason, the pressure distillation method has been almost entirely superseded by the continuous tube furnace which has the advantages of high capacity, reduced coke-formation, increased fuel efficiency, and, most important, ability to operate under very high pressures. Two well-known liquid-phase processes are those of Dubbs, using pressures of 150 to 400 pounds per square inch, and of Cross, operating at much higher pressures, 800 to 1000 pounds per square inch. Other liquid phase processes are associated with the names, Holmes-Manley, Fleming, Jenkins, and Ellis.

In modern liquid phase operation, as exemplified by the processes of Dubbs and Cross, the charging stock is preheated in a series of tubes ("cracking coils") through which the oil passes at a high velocity. The period of contact of the oil in the cracking coils is maintained sufficiently low to prevent any substantial decomposition of the oil at this stage.[59] The oil thus preheated to the temperature of incipient cracking is passed into a larger chamber (called the "soaker") where its velocity is arrested and cracking is allowed to continue to the desired point. Thus, while the initial heating of the oil takes place in the tubes in which little or no coke is deposited, the actual cracking occurs in the soaking drums, which are so designed as to hold a considerable amount of coke before cleaning out is necessary. In the Cross process the average time of reaction in the soaking drum is about 20 minutes, but this may vary according to the mode of operation. On leaving the soaking drum the products of reaction pass to a low pressure separator, where tar residue separates, and thence to a bubble tower which yields an overhead distillate of gasoline and a higher boiling residue (intermediate in boiling range between the distillate and the separated tarry residue), the latter being recycled.

In the "tube and tank" process developed by Ellis, the oil is first heated to a temperature of about 450° to 540° C. (850° to 1000° F.) by being passed through about one hundred small (4 to 4½ inch) tubes set in a furnace. From these tubes, the oil is discharged into an insulated reaction chamber built outside the furnace. A pressure of 250 to 1000 pounds is maintained on the reaction chamber. The more volatile products of the reaction leave the chamber through a pressure relief valve located at the end of the chamber opposite to that at which the oil enters. After leaving the reaction chamber the volatile products pass through a tar-separator, and thus to a bubble tower in which the lighter and heavier components are separated.

---

[59] This condition is general with respect to the later types of cracking processes. In many of the older types a portion of the cracking coil also served as a soaking zone.

The products of liquid phase cracking consist of gas, gasoline, residual oil and coke. The yields of gasoline depend very largely upon the degree of cracking (or the extent of recycling), the nature of the charging stock, and the operating conditions. In general, larger quantities of gasoline are obtainable from lower-boiling petroleum distillates such as kerosene and gas oil, than from heavy oils such as fuel oils. By excessive cracking, yields of cracked gasoline as high as 70 per cent, based on the charging stock, have been obtained but only at the expense of forming much gas and coke together with a low quality residuum oil. Milder cracking conditions with production of less gas and coke and a higher quality residual oil yield from about 30 per cent to 55 per cent of gasoline, depending upon the character of charging stock. The residual oil from cracking operations can be further separated by distillation into such products as furnace oil, fuel oil, and Diesel oil.

According to Singer[60] the liquid phase cracking of Grozny and Surakhani mazouts and heavy crudes is carried out in Russia in two ways, namely (1) under mild conditions producing principally gasoline and fuel oil, and (2) by prolonged cracking to yield gasoline, coke and gas. The first method gives about 1 per cent of coke and 35 per cent of cracked gasoline, the coke formation being constant for equal gasoline yields, and the second, 57 per cent of motor spirits and 15 per cent of coke.

The formation of coke or carbon during cracking processes is said to be largely eliminated by cracking with superheated steam[61] at 1500 pounds pressure at 425° C. (815° F.). This same effect is secured by cracking liquid hydrocarbons (at 426° to 565° C. and 1000 to 5000 pounds pressure) in the presence of hydrogen, the proportion of the latter and the rate at which the reaction products are cooled precluding appreciable hydrogenation.[61a]

The gasoline obtained by liquid phase processes, i.e., cracking under pressure, differs in important respects from that produced by vapor phase, high temperature cracking. Liquid phase cracked gasoline possesses a lower unsaturated hydrocarbon content and much less tendency to gumming (on account of its lower content of diolefinic and similar reactive hydrocarbon types) than the vapor phase product. On the other hand, its anti-knock value is usually distinctly less than that of vapor phase gasoline and this fact is already exerting considerable influence on the cracking art. The increasing demand for motor fuels of high octane number (far higher, possibly, than is often necessary for most commercial motor engines) is a factor calculated to favor the development of high temperature cracking. However, at the present time liquid phase processes produce the major portion of the world's cracked gasoline supply and vapor phase operation is only in its preliminary stage of development. In order to improve the anti-knock quality of the cracked motor fuel, there is a tendency in liquid phase processes towards operation at higher temperatures.

VAPOR PHASE CRACKING

Vapor phase processes, operating at temperatures in the range 500° to 600° C. at atmospheric or only slightly superatmospheric pressure, possess the disadvantages of high fuel consumption, large production of gases and coke, and heavy up-keep and operating costs. On the other hand, they yield gasolines of high anti-knock value, and on this account, vapor phase operation is likely to undergo considerable expansion and development. The large production of gases rich in reactive unsaturated hydrocarbons by vapor phase processes, though a disadvantage to the refiner, is of profound interest to the chemist.[61b]

[60] *Petroleum,* 1929, 25, 893; 1930, 26, 482; *Brit. Chem. Abs.* **B**, 1930, 848.

[61] Hancock and Boyle, U. S. Patent 1,576,742, March 16, 1926.

[61a] Ayres, British Patent 388,225, 1932; assigned to Gulf Refining Co.; *Brit. Chem. Abs.* **B**, 1933, 340.

Of the older vapor phase processes those of Greenstreet, Rittmann, Hall and Parker were operated under pressures of 60 to 150 pounds per square inch at temperatures above 550° C., while the Alexander and Ramage processes were worked at atmospheric or only slightly superatmospheric pressure.[62]

The Ramage process[63] has been considerably improved and, under the name of the Gyro process, bids fair to attain a measure of popularity. The vapor of the hydrocarbons to be cracked, admixed with steam, is passed over a reducible metallic oxide, in particular ferrous oxide, at temperatures of 550° to 600° C. The proportions of steam and hydrocarbon vapor are such as to avoid oxidation of ferrous oxide to ferric oxide as far as possible, and its reduction to metallic iron. The following reactions are used by Ramage to illustrate the process:

$$\text{(1)}\quad C_nH_{2n+2} + Fe_2O_3 \longrightarrow C_nH_{2n} + 2FeO + H_2O$$

$$\text{(2)}\quad C_{16}H_{32} + 2C_8H_{16} \longrightarrow 4C_4H_8 + 8C_2H_4$$

$$\text{(3)}\quad C_2H_4 + 2Fe_2O_3 \longrightarrow 2C + 4FeO + 2H_2O$$

$$\text{(4)}\quad C + Fe_2O_3 \longrightarrow 2FeO + CO\ \ (550^\circ\ C.)$$

$$\text{(5)}\quad H_2O + 2FeO \longrightarrow Fe_2O_3 + H_2\ \ (500^\circ \text{ to } 600^\circ\ C.)$$

The hydrogen evolved according to reaction 5 is assumed to combine with the unsaturated hydrocarbons formed in reactions 1 and 2. On a commercial scale a positive pressure of a few pounds per square inch was employed and it was necessary to blow the iron oxide with air for a few minutes at the end of every 24-hours working operation. In a later development of this process described by Ramage,[64] heavy oils are passed with 1 to 2 per cent of steam over ferric oxide at 420° to 540° C., the resulting (largely olefinic) vapors with 10 to 20 per cent of steam are again passed over finely divided iron at 620° C. and with a further 20 to 40 per cent of steam the operation is repeated at 700° C. or over. An aromatic motor fuel together with gaseous products (e.g., hydrogen, carbon monoxide, methane and ethane) is obtained.

Recent developments of the older Ramage process in the form of the Gyro process have been described by Wagner.[65] In this process the oil is vaporized, mixed with superheated steam in quantity not exceeding 3 per cent by weight of the vapors and the mixture raised almost instantaneously to the cracking temperature of about 535° C. Reaction is allowed to take place in a converter of parallel tubes which in the past have sometimes been fitted with a catalytic core. The conversion is said to be complete in 2 seconds and the pressure on the system is about 15 to 25 pounds per square inch.[66] Wagner[67] stated that by careful temperature control the formation of carbon or coke and excessive amounts of gas can be minimized. A variation of 5° F. in the reaction temperature, other conditions being constant, is said to cause wide fluctuation in the proportion between fixed gas and motor spirit. Changes in the character of the charging stock exert less influence than the factors of heat transfer and flow and temperature control, and have much less effect than in liquid phase cracking. The yields of products obtained from the Gyro process vary, as might be expected, but the fixed gas yields are always high (at least twice as great as that obtained in ordinary liquid phase operation). By cracking gas oil yields of motor fuel of about 60 per cent and of dry gas of 30 per cent were obtained. The gas produced may be partly converted by pyrolysis into a gasoline of high anti-knock value so that the gasoline yield may be increased to about 75 per cent by this subsequent treatment of the gas. Wagner has given some results obtained in a small plant operating with a wide variety of charging stocks. Distillates ranging from 46.5° to 54.8° A.P.I. gravity with end points within the U. S. motor gasoline limit were obtained in yields of 43 to 64 per cent. The gasoline, obtained from the Gyro process contains 40 to 45 per cent of unsaturated hydrocarbons and about an equal proportion of aromatics, the balance being naphthenes with possibly traces of paraffins.

[61b] Wagner (*Ind. Eng. Chem.*, 1934, **26**, 188) discussed two types of vapor-phase cracking operations: (1) at high pressure at 950° to 1050° F. (exemplified by the de Florez process) and (2) at higher temperatures and low pressure (Gyro process).

[62] The various stages in the development of vapor-phase processes have been described by Auld, *Petroleum Times*, 1929, 21, 99, 158.

[67] *J. Inst. Pet. Tech.*, 1929, **15**, 484; *Nat. Pet. News*, 1929, **29** (17), 40-a.

The deFlorez [68] process, which operates in the vapor phase at temperatures of 565° to 590° C. (1050° to 1100° F.) under a pressure of 80 pounds per square inch, is of interest. Although it is known that the use of increased pressure results in the formation of gasoline of lower unsaturation and diminishing gum-forming properties, deFlorez found that the effect becomes well marked even at pressures of the order of 50 to 60 pounds per square inch and at the temperatures indicated above. Furthermore the anti-knock quality of the gasoline is not appreciably depressed as a result of the reduced unsaturated content. The yields in Table 25 are reported by deFlorez for three typical oils cracked at 1050° to 1100° F. and 80 pounds pressure.

TABLE 25.—*Yields of Three Typical Oils Cracked at 1050° to 1100° F. and 80 Pounds Pressure.*

		Oil	
Yields (per cent)	Pa. Gas Oil	Calif. Gas Oil	Venezuela Crude
Gasoline distillate	61.4	53.9	36.4
Residuum	7.9	18.7	56.0
Gas	29.2	27.0	6.1

Gasoline obtained by this process is said to possess excellent anti-knock qualities.

The deFlorez furnace has been successfully used for "reforming" straight-run paraffinic gasoline to increase its anti-knock property, using a temperature of 925° F. and pressures as high as 1000 pounds per square inch. The recovery of cracked gasoline was as high as 86 to 88 per cent.[69]

A vapor phase cracking process developed by Stockman [70] uses steam or an inert gas to vaporize the oil feed. The oil vapors pass to a reaction chamber where they are cracked by heat from gases heated in a battery of stoves.[71] According to Sachs [72] the principles upon which such a vapor phase process is based are: the complete vaporization of the oil prior to passing to the cracking zone, heating the dry vapors by commingling them with hot inert gases and exposure of this hot mixture of gases to ceramic materials only. The reaction chamber is designed to allow time for optimum conversion per single passage at about 638° C. (1000° F.) and pressure is necessary only to overcome friction to ensure good circulation or to limit gaseous volume. In this process the yields of high anti-knock quality motor fuel vary according to the nature of the charging stock. With gas oil as charging stock, yields of cracked gasoline up to 80 per cent are said to be obtained.[73]

---

[71] Balmer, British Patent 317,508, 1928; assigned to Petroleum Conversion Corporation; *Chem. Abs.*, 1930, **24**, 2283.

[72] *Refiner*, 1930, **9**, (1), 70.

Silicates either alone or impregnated with about 1 per cent of nickel or cobalt,[73a] or chromium or nickel alloys containing small proportions of silicon, zinc, iron, aluminum, molybdenum or titanium [73b] have been suggested as catalysts for the cracking of petroleum oils in the presence of steam.

Other vapor phase processes are those developed by Pratt [74] and by Leamon.[75]

On account of their high content of unsaturated hydrocarbons, particularly those of the diolefinic type, cracked gasolines from high temperature vapor phase operations are difficult to refine and have strong tendencies to gumming. Vapor phase refining with fuller's earth at 600° to 650° F. and 1000 pounds per square inch pressure has been used in the treatment of gasolines from the Gyro process.[75a]

Gaseous Products of Cracking

While practically all cracking processes form quantities of permanent gas (or cracking gas), the yield and composition of the gas so produced depends upon a number of factors, such as the type of plant and its operating conditions, but more particularly upon the temperature and duration of heating. The nature of the charging stock does not appear to influence greatly either the yield or the composition of the permanent gas. Particularly is this true in high temperature, or vapor phase, cracking where the gases produced by cracking such widely different charging stocks as Pennsylvania gas oil and crude shale oil have been found to have similar compositions.

Vapor phase cracking normally yields over 1000 cubic feet of gas per barrel of oil cracked. In contrast, the gas yield from liquid phase cracking varies from 100 to 450 cubic feet per barrel. Normal vapor phase cracking produces roughly the same weight of gas as of motor fuel, but if the temperature of cracking is raised to 700°, or higher, the yield of gas is greatly increased. High temperature cracking, especially of comparatively low grade hydrocarbon materials, for the production of large quantities of gas rich in olefin hydrocarbons, might easily be of economic significance.

The quantities of gas available from cracking operations are very large, and Egloff has estimated that the volume of gas produced by cracking processes in 1927 was of the order of 200,000,000,000 cubic feet. Wagner [76] stated that in a Gyro plant a throughput of 4000 barrels of gas oil produced 5,000,000 cubic feet of gas containing olefin gases to the extent of 1,350,000 cubic feet of ethylene, 800,000 cubic feet of propylene, and 450,000 cubic feet of butylenes. As the cracking process is extended to meet the demands for motor fuel the available supply of these valuable olefin gases will be further increased. Moreover, it appears probable that the cracking process will be ultimately applied to such substances as low temperature coal tar, shale oil, and other low grade hydrocarbon materials.

[76] *J. Inst. Pet. Tech.*, 1929, 15, 484.

It is obvious that vapor phase high temperature cracking processes supply a gas valuable from the point of view of the synthesis of chemical products, since gaseous olefins are its principal constituent. As previously noted, the production of large quantities of gaseous olefins by vapor phase cracking is a fact of prime importance to the chemical industry, since these olefins can be converted into a variety of chemical substances of great industrial value.

COMPOSITION OF CRACKING GAS

The composition of cracking gas depends chiefly upon the temperature of cracking. Liquid phase cracking at temperatures of 450° to 480° C. yields a gas containing large proportions of gaseous paraffin hydrocarbons, comparatively small amounts of gaseous olefins, and only a little hydrogen. Propylene appears to be its principal olefinic constituent, ethylene occurring to a less extent, and practically no diolefins are present. On the other hand, vapor phase cracking gas is relatively rich in olefins (up to 60 per cent of the total), ethylene being the predominating constituent. Moreover, diolefins, chiefly butadiene, are present to the extent of 2 per cent, as well as paraffin hydrocarbons, chiefly methane and ethane, and hydrogen (up to 10 per cent).

Brooks and his co-workers[77] have recorded some analyses of gases taken at intervals during the pressure distillation of Jennings (La.) reduced oil boiling above 265° C., and of paraffin. (See Table 26.) The temperature of the still was, of course, rising throughout.

TABLE 26.—*Analysis of Gases Evolved During Pressure Distillation of Jennings Crude and of Paraffin, under 100 Pounds Pressure.*

	Jennings Reduced Crude			Paraffins		
	I	II	III	I	II	III
Temp. of still ° C.	340	415	422	417	432	437
CO_2	1.2	0.5	0.0	0.0	0.0	0.0
CO	1.2	0.5	1.3	0.0	0.0	0.0
C_nH_{2n}	15.4	15.3	13.0	25.4	37.0	33.5
H_2	0.0	4.0	4.4	0.3	0.9	3.0
C_nH_{2n+2}	81.5	79.7	81.3	74.3	62.1	63.5

Egloff[78] recorded the analyses of some gases obtained from liquid phase cracking (Dubbs process). The majority of these analyses indicate a rather high proportion of paraffin hydrocarbons (about 73 to 88 per cent). Ethylene, propylene and butylene appear to be the principal olefins in such gases and some hydrogen is also present.

A typical analysis of a vapor phase cracking gas from the Gyro process made by Wagner[79] is given in Table 27.

TABLE 27.—*Analysis of a Vapor Phase Cracking Gas from the Gyro Process.*

Constituent	Per Cent	Constituent	Per Cent
$CO_2 + H_2S$	0.25	Propylene	16.00
CO	0.15	Butylenes	9.00
H_2	7.00	Butadiene	1.00
Ethylene	27.00	Saturated hydrocarbons	39.00

---

[77] Brooks, Bacon, Padgett, and Humphrey, *Ind. Eng. Chem.*, 1915, 7, 180.

[78] See Rogers, "Manual of Industrial Chemistry," 5th Edition, D. Van Nostrand Co., New York, 1931, 878.

[79] *Loc. cit.* These results obtained with a Pennsylvania gas oil. The hydrogen sulphide content of the gas will vary with the sulphur content of the charging stock.

Wagner, in a later contribution,[80] gave the analyses of typical gases from the vapor phase (Gyro) and liquid phase (Cross) processes as shown in Table 28.

TABLE 28.—*Analyses of Gases from the Gyro and Cross Processes.*

	Cross Process	Gyro Process
	Per Cent	
Methane + hydrogen	46.3	35.4
Ethylene	1.2	22.9
Ethane	16.6	13.3
Propylene	5.3	18.1
Propane	16.2	0.0
Butenes and butadiene	4.3	5.5
Butanes	6.1	1.4
C_5 and heavier	3.7	3.4

There thus appears to be little or no propane in the gases from the Gyro process, but there is some doubt as to the accuracy of this determination. It is believed possible that there may be cycloparaffins (cyclobutane) present, a point not settled definitely. Isobutene and butadiene are also present as well as 1-butene and 2-butene, but the quantitative relationships existing between these compounds are not yet known. Wagner further stated that, contrary to previous reports on the subject, it is now known that some effect upon gas composition is caused by changing the charging stock.

Dunstan[81] quoted the following figures for the unsaturated hydrocarbon content (amounting to 55 per cent of the total gas) in a vapor phase cracking gas:

Constituent	Per Cent	Constituent	Per Cent
Ethylene	54.0	Amylenes	1.7
Propylene	28.0	Higher olefins	6.1
Butylenes	9.0	Butadiene	1.2

Markovich and Pigulevski[81a] divided the gases from the vapor phase cracking at 580° to 620° C. of a Russian crude oil into 3 fractions, viz.: (I) a light fraction consisting of fixed gases and representing 20 per cent by weight of the total gaseous material; (II) a wet gas condensate representing 76.5 per cent of the total; and (III) gases remaining dissolved in the gasoline fraction and representing about 3.5 per cent of the total. The compositions by weight of these three fractions are given in Table 29.

Romoli-Venturi[82] reported that by compressing the gases formed during the cracking of petroleum residues (mazout, fuel oil, and other fractions) liquid hydrocarbons, amounting to 5 to 10 per cent of the original material, are obtained. These hydrocarbons, as indicated by the analysis of their bromine and hypochlorous acid reaction products, consist almost entirely of hydrocarbons of the diolefin and diacetylene series.

Thus vapor phase cracking gas is invariably a complex mixture containing paraffins, olefins, diolefins, hydrogen, and probably a little acetylene as well as sulphuretted hydrogen and carbon monoxide. It has been stated that of the butylenes present in vapor phase cracking gas, isobutylene predominates over its isomers.

Isobutylene	3.0	10.3	40
Amylenes and higher unsaturated hydrocarbons	—	2.5	—

Lewis-Dale[83] has isolated a monoalkylacetylene (probably ethyl- or isopropylacetylene), amylenes, benzene and toluene from the liquid hydrocarbons obtained in the compression of oil gas, i.e., illuminating gas made by the high temperature (about 1500° to 1700° F.) cracking of gas oils. Other unsaturated hydrocarbons were present, but as they readily polymerized their identification was impossible. This polymerization, resulting in the formation of a gummy, resin-like residue, renders difficult the production of a satisfactory motor fuel from the compression liquid.

CRACKED GASOLINE

The aim of commercially operated cracking processes is the production of lower boiling liquid hydrocarbons, usually those boiling within the gasoline range. The most important difference in composition between the synthetic cracked gasolines, produced by thermal degradation, and ordinary straight-run gasolines is the presence of considerable proportions of unsaturated hydrocarbons in the former and of traces only in the latter. The chemical composition of cracked gasoline depends upon a number of factors, most important of which are operating conditions (temperature, pressure, and duration of cracking) and the character of the charging stock.[83a] In a general way, the effect of increasing the temperature of cracking is to increase the percentage of unsaturated hydrocarbons in the cracked product. With increasing temperature of cracking, diolefins are produced in increasing proportions, and at still higher temperatures aromatic hydrocarbons are formed preponderatingly at the expense of the unsaturated hydrocarbons. Naphthenes (cyclopentane and cyclohexane derivatives) are present in considerable amount in most cracked gasolines made at lower temperatures, but at higher temperatures these largely undergo decomposition into aromatics. Relatively large proportions of paraffins are usually present in gasolines produced by cracking at low temperatures but at higher temperatures these are greatly reduced in quantity and vapor phase cracked gasolines generally contain smaller proportions of paraffin hydrocarbons. As might be expected, the character of the charging stock exerts considerable influence on the composition of the gasoline produced at low temperatures (i.e., in liquid phase operations) but at higher temperatures this effect is minimized by the occurrence of overwhelming secondary changes.)

---

[83] *J.S.C.I.*, 1925, 44, 189T.

[83a] Analyses of gasolines obtained on cracking various petroleum oils are given by: Ionescu, *Bul. chim. soc. romane chim.*, 1930, 33, 37; *Chem. Abs.*, 1932, 26, 5407; Korovatzkii, *Neft. Khoz.*, 1932, 22, 217; *Chem. Abs.*, 1932, 26, 4456; Sager, *Petroleum*, 1933, 29 (15), 1; *Brit. Chem. Abs.* B, 1933, 452; Piguzov, *Acta Univ. Asiae Mediae (Tashkent)*, 1932, Ser. VI, No. 5; *Chem. Abs.*, 1933, 27, 4383.

The influence of increased pressure is to reduce the unsaturated hydrocarbon content of the cracked gasoline, probably by speeding up polymerization. However, this effect is reversed at still higher pressures, according to Frolich.[84] The pressure factor never exerts such a marked influence on the unsaturated content of the gasoline as does the temperature factor.

A large number of analyses of cracked gasolines produced from various charging stocks under various conditions have been published but it would be of little value to reproduce such analyses since in most cases the fundamental cracking conditions have been incompletely specified and the analytical methods employed are capable of yielding results only approximately accurate. Egloff[85] gave figures for the composition of various cracked gasolines from the Dubbs process showing that the unsaturated hydrocarbon content varies from 10 per cent to about 30 per cent and averages about 20 to 25 per cent. The proportions of the other three principal types of hydrocarbons appear to vary with the character of the charging stock, but the paraffins average 30 to 40 per cent and the aromatics about 20 per cent, although there may be wide deviations from these figures. According to Egloff,[86] the gasoline obtained by cracking a Californian kerosene under 14 to 21 atmospheres below 500° C. contained 17.3 per cent of olefins, 18.4 per cent of aromatics, 20 per cent of naphthenes, and 44.3 per cent of paraffin hydrocarbons. Garner[87] gave the composition for various liquid phase cracked gasolines shown in Table 30.

TABLE 30.—*Composition of Liquid Phase Cracked Gasolines.*

* From mixed base crude and cracked at 150 lbs. per sq. in.

The gasolines produced by *high temperature vapor phase cracking* are characterized by a higher content of unsaturated hydrocarbons (up to about 50 per cent) and aromatics, with only small amounts of paraffin hydrocarbons. For gasoline produced by vapor phase cracking in a Gyro unit, Wagner gave the composition, 45 to 50 per cent of olefins and diolefins and 40 to 45 per cent of aromatics, with the remainder naphthenes and only a trace of paraffins. The percentage of unsaturated hydrocarbons in vapor phase cracked gasolines does not usually exceed about 50 per cent, but distillates of such gasolines may have a higher unsaturated content.[88] A vapor phase cracked gasoline obtained by cracking light solar oil at a maximum temperature of 600° C. and a pressure of 100 pounds per square inch (contact time, 10 minutes) in a full-sized cracking still was found by Payne and Lowy[89] to possess the approximate composition: 35 per cent olefins, 17 per cent aromatics, 26 per cent naphthenes, and 22 per cent paraffins. The percentage of olefins was highest (over 40 per cent) in the fractions of this gasoline boiling below 100° C. and declined rapidly with rising boiling point.

[88] Thus Garner (*J. Inst. Pet. Tech.*, 1928, **14**, 731) stated that a light aviation spirit, produced by the Lodge-Tinker vapor phase process, was found by him to have an olefin content of over 85%.

[89] *Ind. Eng. Chem.*, 1932, **24**, 432.

Very little work has been reported on the identification of pure saturated and unsaturated hydrocarbons in cracked gasolines. It is to be expected that the monolefins present in cracked products are principally of the branched-chain type, which are known to be more stable thermally than the corresponding straight-chain compounds. The diolefins in cracked gasolines made at higher temperatures appear to be conjugated unsaturated hydrocarbons both acyclic and cyclic, such as butadiene and its homologues, and cyclopentadiene. The naphthenes are mainly cyclopentane and cyclohexane derivatives (with a possible preponderance of the former type) but the presence of cyclobutane hydrocarbons is not improbable.

Brame and Hunter[90] conducted a very careful examination of the light fraction (boiling up to 120° C.) of a gasoline produced by cracking a Russian kerosene in a Cross cracking plant. The specific gravity of this fraction was reported as 0.751, and it contained 27.20 per cent unsaturated hydrocarbons, 4.97 per cent aromatic hydrocarbons, and 67.83 per cent (by difference) of saturated hydrocarbons. It was fractionated into eleven different fractions which were found to have the approximate compositions shown in Table 31.

Table 31.—*Composition of Fractions of Gasoline from a Russian Kerosene (Cross Process).*

Fraction ° C.	Unsaturates	Benzene	Toluene	Naphthenes	Paraffins

* As benzene and toluene.

By very careful fractionations and separation of the olefins as bromides, Brame and Hunter were able to obtain a sufficiently satisfactory separation of a number of hydrocarbons and identification of the following substances was regarded as being established:

Paraffins. Both paraffins and iso-paraffins were present including hexane, heptane, and the isohexanes, trimethylethylmethane and diisopropyl, with indications of pentane, isopentane, and isoheptanes.

Naphthenes. These occurred with the paraffins, being present in nearly equal amounts. Methylcyclopentane, cyclohexane, dimethylcyclopentane, and methylcyclohexane were isolated.

Olefins. These were the predominating unsaturated hydrocarbons in the lower-boiling fractions, and the presence of 3-, and 2-methylpentenes and of 4-, and 5-methylhexenes was probable. Olefins of the type $RCH{=}CH_2$ appeared to be absent. Cyclic olefins predominated in the unsaturated compounds in the higher-boiling fractions. Indications of the presence of *diolefins* were obtained in the first fractions with definite evidence of piperylene (1-methylbutadiene). Cyclic olefins (e.g., methylcyclopentene) predominated in the unsaturates boiling from 90° to 120° C.

Aromatics. Small percentages of aromatics, considered as benzene and toluene, were present in the gasoline investigated.

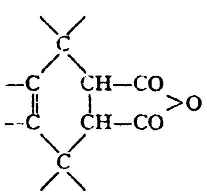
---

[90] *J. Inst. Pet. Tech.*, 1927, 13, 794.

Ivanov[90a] analyzed a cracked gasoline, boiling between 20° and 150° C. He found that 25 per cent of the fraction boiling from 60° to 70° C. and 40 per cent of the fraction boiling at 120° to 125° C. consisted of unsaturated n- and iso-hydrocarbons. About 30 per cent of the gasoline was naphthenes. He was also able to show that 3-hexene, 1- and 2-heptene, 3-octene, benzene, toluene and xylenes were present.

It is interesting to note that Payne and Lowy[91] inferred the probable presence of methylcyclobutane in a fraction, boiling at 29.4° to 35.0° C., of a vapor phase cracked gasoline. The variation in the unsaturated hydrocarbon content of this cracked gasoline with the boiling point of its various fractions before and after a second heat treatment (at 300° C. and 68 atmospheres for 6 hours in a steel bomb) was shown.

Birch and Scott[92] recorded the results of an investigation of the conjugated diolefins present in a vapor phase cracked gasoline, making use of the reaction of such hydrocarbons with maleic anhydride to form, in many instances, crystalline derivatives[93] of the type,



Butadiene, piperylene, isoprene and cyclopentadiene were all present in the lower boiling fractions of this gasoline and could be readily separated and identified. Attempts to isolate the corresponding derivatives from the dimethylbutadiene fraction of the gasoline were unsuccessful, probably on account of the complex nature of the fractions examined.

Markovich[94] described the results of a careful rectification of the lower-boiling liquid and volatile products from cracking crude oil in the vapor phase at high temperatures ("blau" gas cracking). The compression product consisted of 2 per cent of propylene, 19 per cent of butylenes, 28 per cent of C_5 hydrocarbons (up to 90 per cent unsaturates), 22 per cent of C_6 hydrocarbons (up to 85 per cent unsaturates), 17 per cent of benzene, 12 per cent of higher hydrocarbons, and some butadiene and butane.

Chapter 4

Production of Unsaturated Hydrocarbons by Pyrolysis—Olefins, Acetylene and Diolefins

The action of heat on various saturated hydrocarbons frequently yields unsaturated compounds and in certain instances leads to rearrangements within the molecules. The mechanism of these reactions has not been definitely established. Nevertheless, Dunstan, Hague and Wheeler[1] have concluded, from a consideration of their work on paraffin hydrocarbons ranging from ethane to hexane, that the primary decompositions are represented by the rupture of the chain at any point, with the simultaneous production of an olefin and the complementary lower paraffin, or (as a limiting case) hydrogen. The tendency to eliminate hydrogen, they found, decreases as the size of the molecule increases. They also stated that the main primary reactions common to ethylene, propylene and the butylenes involve the formation of olefins of either two or four carbon atoms or both. Ebrey and Engelder,[2] from their investigations of the pyrolysis of propane, have also shown that a carbon-to-carbon linkage breaks more readily than a carbon-to-hydrogen linkage. From his work on the cracking of Rangoon paraffin in the vapor phase, Heymans[3] concluded that cracking occurs at the end of the hydrocarbon chain and then proceeds from point to point along the chain. These primary decomposition reactions are followed generally by purely synthetic reactions occurring under the action of heat and resulting in the formation of hydrocarbons of increased molecular weights, such as those of the aromatic series.

From these considerations it is seen that maximum yields of olefins and diolefins require careful regulation of the conditions of cracking to prevent change or degradation of the unsaturated hydrocarbons first formed. The following account will discuss first the formation of the individual olefins from various raw materials, and later the pyrolytic production of acetylene and the diolefins. The latter are important as possible starting materials for the synthesis of rubber substitutes, an account of which will follow in Chapter 26.

ETHYLENE

Ethylene is an important product of the cracking of hydrocarbons, even of methane. It occurs in the gases produced in the commercial cracking of petroleum oils. Low temperature cracking (in the liquid phase) at about 480° C. yields a gas comparatively poor in olefins. Of the olefins thus formed propylene seems to be the most important constituent. Generally, the ethylene content of liquid phase cracking gas does not exceed 5 per cent. On the other hand, high temperature vapor phase cracking yields a gas relatively rich in olefin hydrocarbons, of which ethylene is predominant. High temperature cracking at about 600° to 650° C. normally yields a gas containing 50 per cent or more of unsaturated hydrocarbons of which about 25 per cent is ethylene. Large quantities of ethylene will become available with the wider adoption of vapor phase cracking for the manufacture of motor fuels with high antiknock value.

[1] *J.S.C.I.*, 1931, **50**, 313T.

[2] *Ind. Eng. Chem.*, 1931, **31**, 1033.

[3] *J. Inst. Pet. Tech.*, 1930, **16**, 661; *Chem. Abs.*, 1931, **25**, 1066.

Ethylene may be obtained also by the controlled pyrolysis of the paraffin hydrocarbons of natural gas and light gasoline. The researches of numerous workers in this field have shown that the lower paraffin hydrocarbons containing from 2 to 5 carbon atoms are especially suitable for the pyrolytic preparation of ethylene. At the high temperatures necessary for the pyrolysis of methane (1000° C. and higher), ethylene is largely converted into aromatic hydrocarbons and other substances. Thus, Stanley and Nash[4] reported that only 1 to 2 per cent of ethylene and 2 to 3 per cent of acetylene were obtained by the pyrolysis of methane at 1100° to 1150° C. The yield of acetylene increased with rising temperatures of pyrolysis but lower temperatures appeared necessary for larger production of ethylene. Probably the best temperature for the conversion of methane into ethylene is in the range of 1050° to 1100° C.

According to de Rudder and Biedermann,[5] the maximum yield of ethylene from methane, namely 4 per cent of the gaseous products, is obtained by pyrolysis at 1200° C. under 100 mm. pressure. The gas obtained under these conditions also contains 2.5 per cent acetylene. The results of Frolich, White and Dayton[6] on the pyrolysis of methane under reduced pressure in silica tubes at temperatures above 1000° C. showed that the percentage of ethylene in the reaction gases is at a maximum of almost 2 per cent at about 1100° C. under 33 to 102 mm. pressure, and that the pressure or time of contact exerts little influence on this value. Padovani and Magaldi[7] reported that in the pyrolysis of methane at 1000° to 1250° C. in silica tubes, dilution with hydrogen increases the formation of ethylene and acetylene at lower rates of flow, although the effect is reversed at higher rates. On the other hand, Smith, Grandone and Rall[8] found that the percentage of ethylene and acetylene in the gaseous reaction products was increased by dilution of the methane with either hydrogen or nitrogen. Warren[9] investigated the influence of pressures higher than atmospheric on the percentage of total unsaturated hydrocarbons in the gaseous products when pyrolysis was conducted in silica tubes. Temperatures of 902° to 1122° C. and pressures as high as 104 atmospheres were employed. The yield of unsaturated hydrocarbons was found to diminish with increasing pressure. Storch[10] examined the pyrolysis of methane with carbon filaments at 1457° to 2000° C. in bulbs cooled by liquid nitrogen and at —183°, —78°, and 0° C. A 95 per cent yield of ethane is found with liquid nitrogen, at —183° C. ethylene and acetylene are produced, and at higher temperatures the products are carbon and hydrogen.

It appears, therefore, that only relatively small yields of ethylene may be obtained by the pyrolysis of methane with short heating periods in the temperature range of 1050° to 1200° C. Under these conditions acetylene and other products are formed at the same time. At higher temperatures, acetylene predominates. Inactive heating surfaces (consisting of materials such as silica, porcelain or copper, which do not accelerate the decomposition of methane into its elements) are essential for optimum yields of unsaturated hydrocarbons. The use of gaseous diluents also seems to be advantageous. In view of the high temperatures necessary and the relatively poor conversions obtainable, methane is not a promising material for the production of ethylene.

Ethane is an almost ideal raw material for the pyrolytic production of ethylene. The decomposition of ethane at 675° C. to ethylene and hydrogen was observed by Bone and Coward.[11] The reaction involved, namely,

$$C_2H_6 \rightleftharpoons C_2H_4 + H_2$$

was studied by Pease and Durgan[12] at temperatures of 600° to 700° C. and shown to be reversible and complicated to some extent by other reactions, such as the formation of methane. They obtained values of the equilibrium constant, K, at 600°, 650° and 700° C.

$$K = \frac{[C_2H_4][H_2]}{[C_2H_6]}$$

Frey and Huppke[12a] measured the same equilibrium at temperatures of 400° to 500° C., using air-dried chromic-oxide gel as a catalyst. The values of K obtained by the latter investigators, as well as those by Pease and Durgan, are given below:

Temp. ° C.	400°	450°	500°	600°	650°	700°
K	0.00015	0.00076	0.0032	0.031	0.082	0.20

Cambron[13] passed ethane over an electrically heated carbon rod at 989° C. and found that 50.5 per cent of the entering gas was converted to ethylene and 90 per cent of the ethane decomposing did so according to the above equation.

Elworthy[14] reported that a commercial process has been developed for converting ethane (separated from natural gas by fractionation) into ethylene by cracking in copper, earthenware, or porcelain tubes at about 600° C. The temperatures might possibly be raised at sufficiently high gas velocities (i.e., short heating periods). The occurrence of undesirable side reactions becomes more marked as the temperature is increased. Hague and Wheeler[15] reported, however, that even at 700° C. in the presence of silica heating surfaces about 90 per cent of the decomposed ethane was dehydrogenated to form ethylene, and that the reaction gas contained 21.3 per cent of ethylene and only 2.7 per cent of methane. The ethylene content of the gaseous products of the pyrolysis of ethane was at a maximum of 24.3 per cent in an experiment at 750° C., but the gas also contained 13.3 per cent of methane and 4.7 per cent of higher olefins. This indicated that the efficiency of ethylene production from ethane was lower at 750° C. than at 700° C. In order to limit other reactions, such as the formation of methane, it appears necessary to employ short heating periods at temperatures not above 800° C., dehydrogenating in one passage.

The usual metallic dehydrogenating catalysts (finely divided copper or nickel) might be expected to assist in the conversion of paraffins to olefins. Indications are, however, that although these materials greatly reduce the temperature required for the reaction, they simultaneously catalyze the formation of methane, carbon and hydrogen. Thus, the efficiency of olefin formation is reduced and little advantage apparently accrues from their use. Elworthy[16] found, for example, that when a gas containing 80 per cent of methane and 7 per cent of ethane was passed through tubes containing a catalyst composed of copper oxide, pumice and carbon, the proportion of olefin in the gaseous products was very low. He concluded that the olefin was formed only from ethane. The best temperature for the reaction was about 800° C. The dehydrogenation of ethane was accelerated by the presence of reduced copper, and a molybdenum trioxide coating on copper bronze was also active.[17]

[14] *Industrial Chemist*, 1928, **4**, 275. This is stated to be the process developed by the Carbide and Carbon Chemicals Corp.

[15] *J.C.S.*, 1929, 378.

Matignon, Kling and Florentin[18] observed that the dehydrogenation of the lower paraffins in the presence of catalysts of pumice impregnated with copper and nickel is favored by low reaction temperatures and short periods of contact. Thus, the exposure of ethane to the action of a nickel-pumice catalyst at 600° C. yielded reaction gases of the following compositions:

Contact Time	Analysis of Reaction Gas	Per Cent by Volume		
Secs.	C_2H_4	H_2	C_2H_6	CH_4
42	14.2	22.0	51.0	12.8
396	12.7	40.7	0.0	49.9

As the molecular weight of the paraffin hydrocarbon increases, there is a greater tendency to pyrolysis into olefins and paraffins of lower molecular weight and the simple dehydrogenation reaction, forming an olefin of the same number of carbon atoms as the original paraffin, is increasingly obscured. Thus, propane undergoes pyrolysis in contact with silica to form methane, ethylene, propylene and hydrogen. According to Schneider and Frolich,[19] in the pyrolysis of propane at 725° C. under atmospheric pressure with short periods of heating (so that 20 to 40 per cent of the propane is decomposed per passage), about 50 per cent of the hydrocarbon decomposed is converted into methane and ethylene according to the reaction

$$C_3H_8 \longrightarrow CH_4 + C_2H_4,$$

and about 40 per cent is dehydrogenated to propylene. Using n-butane, Hague and Wheeler[20] observed that at 650° C. in the presence of silica about 43 per cent of the hydrocarbon decomposed follows the reaction,

$$CH_3CH_2CH_2CH_3 \longrightarrow CH_3CH_3 + CH_2{=}CH_2,$$

36 per cent forms methane and propylene, and 21 per cent is converted to hydrogen and butylene.

In the pyrolysis of these paraffin hydrocarbons considerable ethylene is formed together with propylene and its homologues. The cracking of butane and isobutane is now carried out on a commercial scale for producing a mixture of ethylene and propylene, used in the manufacture of glycols.[21]

Von Piotrowski and Winkler[22] made a special study of the optimum conditions of pyrolysis to olefins of a propane-butane mixture and of a stripped Boryslaw (Poland) natural gas. From the propane-butane mixture (39 per cent propane, 50 per cent butane, and 11 per cent pentane), the yield of olefins with

[22] *Przemysl Chem.*, 1930, **14**, 49, 83; *Petroleum Z.*, 1930, **26**, 763; *Chem. Abs.*, 1930, **24**, 4924; *Brit. Chem. Abs.* **B**, 1930, 309, 850.

more than two carbon atoms was highest at 730° C., and that of the ethylene reached a maximum at about 800° C. The heating period was about 8 seconds, and the conversion to olefins amounted to 70 per cent or more.

According to Smolenski,[23] the pyrolysis of crude naphtha at 600° C. yielded 15 cubic meters of gaseous olefins per 100 kilograms of naphtha, their concentration in the crude cracking gas being 35 to 37 per cent. At 700° C. the olefins formed (mainly ethylene) corresponded to 15 kilograms per 100 kilograms of naphtha (concentration in the gas being 20 to 22 per cent).

Large scale experiments on the production of both aromatic hydrocarbons and ethylene by the pyrolysis of various gaseous mixtures of paraffins (mainly propane and butanes) have been described by Podbielniak.[24] His results clearly show the practicability of using these gaseous hydrocarbons as raw materials for the manufacture of ethylene. Pyrolysis was effected in a plant capable of handling about 25,000 cu. ft. of gas per day. In the treatment of hydrocarbon gases rich in propane and butanes, e.g., stabilizer gas, the optimum temperature for the production of aromatic hydrocarbons was 1650° to 1700° F. (900° to 925° C.), and the maximum yield of ethylene was obtained at 1500° to 1550° F. (815° to 845° C.). By careful control of operating conditions, special alloy metal reaction tubes could be used for either reaction. The results of two large scale tests on the manufacture of ethylene from gaseous paraffins are summarized below:

Composition of Raw Gas Per Cent by Volume				Outlet Temp. of Cracked Gas, ° F.	Expansion Ratio of Cracked to Raw Gas	Per Cent C_2H_4 in Cracked Gas
CH_4	C_2H_6	C_3H_8	C_4H_{10}			
1.7	9.5	76.2	10.0	1,550°	1.709	26.8
2.2	10.2	—	87.6	1,525°	1.520	26.0

For maximum yields of ethylene, recycling the reaction products after the removal of the ethylene is particularly advantageous. On the assumption that ethylene is removed after each stage of pyrolysis and that propylene and heavier hydrocarbons are recycled through the furnace, Podbielniak calculated from the data of the second experiment in the preceding table that the total volume of ethylene obtainable from 1000 cu. ft. of gas in five successive passages through the furnace is about 636.6 cu. ft., made up as follows:

	Cu. Ft. of Ethylene from 1000 Cu. Ft. of Raw Gas
First Passage	395
Second Passage	152
Third Passage	58.5
Fourth Passage	22.5
Fifth Passage	8.6
Total	636.6

In the course of an investigation of the effect of time and temperature upon the cracking of a representative Mid-Continent gas oil, Geniesse and Reuter[25] determined the yields of ethylene and other unsaturated gaseous hydrocarbons produced at various temperatures and at different periods of contact. The gas oil was pyrolyzed in the vapor phase in reaction chambers of pyrex glass. Some of the results of these investigators are given in Table 32.

(d) Total unsaturated hydrocarbons, % by volume . .	56	55	57	57	59	59	58	50	58	54

* The time-temperature index is defined by the expression $\left(2^{\frac{T-480}{17}}\right) \times t$, in which *T* is the cracking temperature in °C. and *t* the time in minutes. (See also Chapter 3.)

It will be seen from the table that the greatest ethylene production was obtained at 700° C., the highest temperature reported. With a contact period of 0.023 minute at 700° C., gas oil yielded 65.5 per cent by weight of gaseous products containing 28 per cent by volume of ethylene, corresponding to an overall conversion of gas oil into ethylene, of about 17 per cent by weight per passage.

To transform saturated hydrocarbons and petroleum distillates into ethylene, higher temperatures are required than when propylene and the butylenes are the desired products. A review of pyrolytic processes for making olefins indicates that the raw materials generally employed are gaseous paraffin hydrocarbons (e.g., coke-oven gas or natural gas) or the higher boiling petroleum fractions.

In the products from cracking paraffin oils, Tichy[26] found both unsaturated and aromatic hydrocarbons. With the aid of metallic oxide and chloride catalysts (the best being aluminum chloride and stannic oxide), the decomposition time was decreased by one-half and the yields of low boiling fractions were increased.

Unsaturated aliphatic hydrocarbons, such as ethylene and acetylene, may be produced from paraffin hydrocarbons, especially from methane, by passing the latter over catalysts, e.g., salts or hydroxides of the alkaline earth metals, magnesium, or beryllium, compounds of selenium, tellurium, or thallium, or activated carbon or silica, at temperatures of 700° to 1000° C. A sufficiently rapid rate of flow should be used to preclude further condensation of the initial products to aromatic hydrocarbons.[27] If the gaseous products are quickly removed from the reaction zone, acetylene is said to be the principal product at very high temperatures and ethylene at somewhat lower ones. By arranging the materials in the reaction chamber to form straight channels of uniform cross-sections, irregularities in gas velocity, which result in carbon deposition, are avoided.[27a]

Folliet[28] converted methane into ethylene and other olefins to the extent of 80 per cent by heating a thin stream of the gas (to secure uniform temperature) to 950° C. followed by sudden cooling to atmospheric temperature. The pressure in the apparatus was maintained at 20 mm.

Ethane fractionated from natural gas was used by Haynes and Curme[29] as the raw material for the production of ethylene by pyrolysis at temperatures above 500° C. Haynes and Curme[30] later extended this process to the making of other olefins. The individual gaseous paraffins are prepared in a state of substantial purity by fractional condensation and rectification of natural gas, and are subjected separately to heat treatment under the optimum conditions for conversion to olefins. The products of thermal decomposition are combined, and from this mixture at least one of the paraffins originally treated, e.g., ethane or propane, is isolated by fractionation for reuse in a subsequent heat-treatment.

The separation of ethylene from ethane in the gases from coal distillation can be effected by absorbing ethylene in sulphuric acid.[31] The residual ethane is subjected to pyrolysis to yield ethylene and hydrogen, the ethylene being recovered by solution in the acid.

An unusual method for making ethylene from methane is described by Agnus,[32] who passed carbon disulphide and methane over heated pumice or activated carbon and substances which combine with sulphur, such as copper or zinc.

According to van Peski,[33] propane may be converted into a mixture of ethylene and methane by passing it over granulated calcium, iron or tungsten carbide at 600° to 800° C. The catalyst remained active for several days. Molybdenum mixed with pumice catalyzes the decomposition of propane to methane and ethylene still more rapidly. Evidently carbides and molybdenum on pumice exert a selective catalytic influence on the reaction,

$$C_3H_8 \longrightarrow C_2H_4 + CH_4$$

which is merely one of the several modes of decomposition of propane by heat treatment. A gas oil, boiling at 220° to 340° C., when treated in this manner yielded a gas containing a large proportion of unsaturated hydrocarbons and a liquid condensate boiling between 60° and 180° C.

The pyrolysis of cracked petroleum fractions solely by superheated steam under pressure has been proposed by Fenton.[34] Subjecting tar oils, having a boiling point of 250° C. and higher, to destructive distillation at temperatures between 800° and 900° C. in the presence of steam produces gases of high olefin content (40 to 50 per cent).[35] The predominating olefinic constituent is ethylene, of which 88 to 90 per cent can be recovered by passing the gases once through activated charcoal. Suida[36] described a similar process in which gases rich in olefins are obtained by the destructive distillation of crude tar in the presence of steam.

PROPYLENE

The gases from commercial cracking operations contain appreciable proportions of propylene, which is being utilized for the manufacture of isopropyl alcohol and other products.[37] In the gases from low temperature (liquid phase) cracking, propylene appears to be the main olefinic constituent, although the actual percentage is not normally very high (maximum about 10 per cent). In high temperature (vapor phase) cracking the actual percentage of propylene is somewhat increased, but this gas is associated with a much greater proportion of ethylene. According to Wagner,[38] a typical liquid phase cracking gas (Cross process) contains 5.3 per cent of propylene and, the gas from a vapor phase cracking (Gyro) process has a propylene content of 18.1 per cent.

Although propylene is an important product of the pyrolysis of many petroleum distillates and higher hydrocarbons, temperatures somewhat lower than those used in making ethylene are required for its manufacture, on account of the greater tendency of propylene to undergo decomposition with the formation of, among other substances, ethylene itself. No precise information on this matter appears to be available but temperatures of about 600° C. seem to be the most favorable for the pyrolysis of petroleum oils to propylene. Thus, according to Dobryanski, Arkhangelski and Stepanyan,[39] who investigated the pyrolysis of various petroleum fractions in a copper tube at 550° to 750° C., the highest yields of propylene were obtained from solar oil at temperatures of 600° to 650° C. Above this range there was a tendency for the propylene to undergo decomposition. Moreover, the yield of propylene was not increased by using either nickel or iron as catalysts. Under the best conditions 100 grams of solar oil (initial boiling point, 305° C.) gave about 13 grams of propylene.

The obvious starting material for making propylene is propane, but Hague and Wheeler[40] and others have shown that this hydrocarbon can decompose during pyrolysis in at least two ways:

$$(1)\quad CH_3CH_2CH_3 \longrightarrow CH_4 + CH_2{=}CH_2 \text{ (demethanation)}$$

$$(2)\quad CH_3CH_2CH_3 \longrightarrow CH_3CH{=}CH_2 + H_2 \text{ (dehydrogenation)}$$

The first reaction, yielding methane and ethylene, was found by Hague and Wheeler to occur to the extent of about 60 per cent (calculated on the propane decomposed) at 700° C. in silica tubes and the second, forming propylene and hydrogen, to the extent of nearly 40 per cent. At temperatures above 700° C. secondary changes begin to intervene.

Ebrey and Engelder[41] observed that the pyrolysis of propane in silica tubes gives varying proportions of hydrogen, methane, ethane, ethylene and propylene and that the proportion of hydrogen increases with rising temperature. Unsaturated hydrocarbon formation reached a maximum at 770° C. Catalysts containing nickel, cobalt, chromium, or iron increased the proportion of hydrogen and methane formed.

It has been shown further by Schneider and Frolich[42] that the relative extents to which dehydrogenation and demethanation reactions proceed during the pyrolysis of propane (at 725° C. under atmospheric pressure in silica tubes) are practically the same for all degrees of propane decomposition from zero to about 40

[37] For the preparation of isopropyl alcohol see Chapter 14.

per cent. In the non-catalytic pyrolysis of propane, ethylene is always produced in amounts in excess of propylene even at short times of contact when only a small quantity of the propane is decomposed.

The possibility of selectively accelerating dehydrogenation at the expense of demethanation is indicated by the work of Boeckler.[43] He observed that the production of propylene was greatly increased by using a catalyst consisting of 78.5 molar per cent zinc and 21.5 molar per cent chromium. With this catalyst a larger yield of propylene was obtained at 655° C. than without it at 730° C., even though the rate of flow of gas at the latter temperature was one-fourth that at 655° C. At temperatures as low as 520° C., propane diluted with 67 per cent of nitrogen yielded 11 per cent propylene. Matignon, Kling and Florentin[44] reported that in the presence of a catalyst of pumice impregnated with copper the decomposition of propane at 500° C. yields only a negligible proportion of ethylene. The formation of propylene is favored at all temperatures by short times of contact with the heated catalyst. With prolonged periods of contact, methane and ethylene become the main reaction products.

The results of von Piotrowski and Winkler[45] on the pyrolysis of a stripped Boryslaw natural gas containing propane and methane in the volume proportions of 22 to 78 appear to indicate that almost quantitative conversion of propane into propylene can be achieved at about 780° C. with a contact period of 11 seconds in the presence of an excess of methane as a diluent. It is to be expected, from purely theoretical considerations, that dilution of propane with excess methane should favor the formation of propylene, since such dilution would tend to suppress the demethanation reaction.

In most thermal decompositions the propylene formed is mixed with other olefinic gases. The yield of this olefin increases with rising temperature up to a certain point, above which it falls off and ethylene becomes the predominant olefin in the cracking gas.

Haynes and Curme[46] subjected propane, which has been separated in substantially pure form from a gaseous mixture containing it, to pyrolysis under optimum conditions for dehydrogenation to propylene. Propane and propylene are isolated from the reaction products, and the propane returned to the pyrolysis cycle.

Heinemann[47] has described a method for the manufacture of propylene by the direct combination of methane with acetylene, according to the reaction,

$$C_2H_2 + CH_4 \longrightarrow C_3H_6$$

The process involves the passage of equal volumes of methane and acetylene through tubes containing such contact materials as copper wool, copper gauze, aluminum or magnesium turnings coated with a metal like platinum, or a copper-platinum-pumice catalyst. The temperature ranged from 100° to 200° C., depending upon the catalyst employed. The use of inert gaseous diluents, as for example carbon dioxide or nitrogen, is advantageous. The yield of propylene is said to be approximately 78 per cent.

According to Ellis,[48] fractions of casinghead gasoline consisting principally of pentane may be cracked to yield gaseous olefins, advantageously in the presence of catalysts of nickel, copper, or brass. At about 720° C., a pressure of about 0.5 atmosphere, and a gas velocity of 3 to 40 cu. ft. per hour per sq. in. of cross-sectional area of the cracking tube, a 32.8 per cent yield of olefins, chiefly propylene, was obtained. Ethylene was formed to the extent of 9.6 per cent.

Propylene was made by the pyrolysis of butane or isobutane in the presence of a catalyst, such as copper, at 700° C. by Gerstmyer and Clayton.[49] Best results were secured when the rate of gas flow was such that the expansion ratio of the inlet to exit gases was about 1 to 1.29.

BUTYLENES AND HIGHER OLEFINS

Butylenes are produced to a considerable extent in commercial cracking. Low temperature cracking yields a gas containing about 4 per cent of butylenes and the butylene content of vapor phase cracking gas varies from 5 to 9 per cent. It is known that all three butylenes are present in cracking gas but the relative proportions of these isomers apparently has not been determined. According to Wagner[50] large quantities of isobutylene and somewhat smaller amounts of butadiene are produced by vapor phase processes.

The direct thermal dehydrogenation of n-butane to 1-butene is apparently not a satisfactory method for the manufacture of this olefin. Hague and Wheeler[51] and Hurd and Spence[52] have found that dehydrogenation takes place to a small degree, but that reactions involving the splitting of the molecule predominate. According to Hurd and Spence, the thermal dehydrogenation of isobutane to isobutylene is an important reaction in the region of 600° to 700° C., at which temperatures methane and propylene are formed simultaneously.

PRODUCTION OF MIXTURES OF GASEOUS OLEFINS

The increasing value of the lower olefins in organic synthesis has stimulated interest in their production and much activity has been displayed in their utilization.[53] Bowen[54] discussed their importance in the manufacture of such products as ethyl, isopropyl, secondary and tertiary butyl and amyl alcohols; ethylene glycol; ethers, esters and ketones derived from these alcohols; triethanolamine; and synthetic lubricating oils. The methods of making these compounds and their uses are discussed in succeeding chapters.

As raw materials for the pyrolytic preparation of olefins and olefin mixtures, bituminous coal, gaseous paraffin hydrocarbons, and petroleum distillates have been investigated. The use of lower paraffin hydrocarbon gases, or mixtures which contain them, has attracted attention because of their abundance and relative cheapness. Large quantities of propane and butanes, obtained as by-products from the stabilization of natural-gas gasoline, are available and would appear to be ideal starting materials for making olefins, particularly ethylene and propylene.

In this connection the investigations of von Piotrowski and Winkler[55] on the pyrolysis of saturated gaseous hydrocarbons is of interest. The furnace employed in their work consisted of a double reaction tube heated in a bath of molten lead, the ingoing gases being preheated in the inner reaction tube and cracked in the outer one. From a mixture of propane (39 per cent), butanes (50 per cent) and pentanes (11 per cent) at an optimum contact time of about 8 seconds, the yield of unsaturated gaseous hydrocarbons having more than two carbon atoms was a maximum at 730° C. The optimum temperature for ethylene formation was 800° C. Temperatures of 700° to 760° C. gave the highest total yields of unsaturated gaseous hydrocarbons.

Frey and Hepp[55a] cracked butane, isobutane, pentane, isopentane, 2,2-dimethylpropane, hexane and 2,3-dimethylbutane at 400° to 575° C. The primary products of decomposition are methane and an olefin, or a paraffin and an olefin, or two olefins and hydrogen.

The work of Podbielniak[56] on cracking gaseous paraffins, such as propane-butane mixtures, has been previously noted. It need only be mentioned again that, in cracking for maximum yields of olefins, Podbielniak stressed the advantages of recycling the gases after removing the olefins formed during each cycle. For example, when ethylene is the desired product, best results were obtained by operating a continuous recovery and recycling process in which the ethylene is extracted after each cycle and the residual heavier hydrocarbons (propane, propylene, and others) are mixed with the fresh charging stock.

Cambron and Bayley[56a] investigated the pyrolysis of ethane, propane and other hydrocarbons under conditions of streamline and turbulent flow in externally heated quartz tubes. With turbulent flow, higher rates of conversion to olefins were found.

The pyrolysis of liquid hydrocarbons and petroleum distillates to gaseous olefins has been the subject of a number of investigations. Although commercial cracking operations, particularly those at higher temperatures in the vapor phase, always yield considerable proportions of gaseous products containing as high as 50 per cent by volume of unsaturated hydrocarbons, their main object is to produce liquid hydrocarbons boiling in the gasoline range (i.e., up to about 200° C.). For this reason gas formation is generally minimized as far as possible. However, cracking as a means of producing gaseous olefins presents possibilities and might be economically feasible in countries where large supplies of such olefins are not otherwise available.

A study of the optimum conditions for producing gaseous olefins from a Pennsylvania straight-run gasoline (end point, 210° C.) by vapor phase pyrolysis at atmospheric pressure was made by Cassar.[57] The reaction vessel used by him consisted of a 3-foot length of 1-inch iron pipe packed with pumice and heated over a length of 30 inches. At a constant rate of feed, corresponding to a time of contact (of the liquid) of 5.66 hours, the total gas formation increased linearly with the temperature. The following empirical relation was found to exist:

$$G = 2.38\,(T - 480)$$

where G = volume of gas evolved per unit (liquid) volume of charge and T = temperature in °C. The proportion of olefins in the gas reached a maximum of 47 per cent by volume at about 600° C., and diminished at both higher and lower temperatures. At the above rate of feed, 135 volumes of gaseous olefins per unit (liquid) volume of feed were obtained at 600° C., corresponding to an optimum

[55a] *Ind. Eng. Chem.*, 1933, 25, 441.
[56] *Oil and Gas J.*, 1931, 29 (52), 22.
[56a] *Canadian J. Research*, 1933, 9, 175; *Chem. Abs.*, 1933, 27, 5172.
[57] *Ind. Eng. Chem.*, 1932, 24, 802.

concentration of olefins (45 per cent) in the gas. Maximum gas production, namely 650 volumes per unit (liquid) volume of feed, was obtained at 700° C. This gas, however, contained a lower proportion of olefins than that obtained at 600° C.

Cassar also determined the effect of varying the contact time on the yield of products at a constant temperature of 600° C. He found the relation between gas production and contact time to be

$$\log_e G = 0.0758\,\mathrm{H} + 5.18$$

in which G = volume of gas per unit (liquid) volume of feed, and H = time of contact (of liquid) in hours. This logarithmic relation indicates that the gas formed per unit of time is proportional to the quantity of gas already formed. This apparently means that a partly gasified (cracked) stock should gasify more readily than an uncracked stock.

It is interesting to note that the results of Gault and Hessel[88] on the cracking of hexadecane (in quartz tubes at various temperatures up to 815° C.) indicate that the volume of gaseous products formed at a constant rate of flow is directly proportional to the cracking temperature. A few experimental results of these investigators, showing the gas yields obtained under different conditions, are given in Table 33.

Little information appears to be available with regard to the conditions necessary for the maximum yields of unsaturated gaseous hydrocarbons from the pyrolysis of petroleum distillates boiling above the gasoline range. Although the complete gasification of certain petroleum distillates to yield fuel gases (the so-called Blau gas and Pintsch gas being examples) has been practiced for many years, such processes are usually operated under conditions which permit the unsaturated hydrocarbon gases formed to undergo further changes. Optimum yields of unsaturated hydrocarbons are therefore not to be expected.

Some information on the gas yields obtained by the pyrolysis of a representative Mid-Continent gas oil in pyrex reaction tubes has been supplied by Geniesse and Reuter.[59] The results of some single-pass experiments at 640° to 700° C., in so far as they relate to gas production, are given in Table 34.

TABLE 34.—*Gas Production in the Cracking of Mid-Continent Gas Oil.*

* Times of contact calculated, assuming the gas laws, from the mean velocity of oil vapor entering tube and that of gases leaving furnace. (a) = 1.9% by weight of coke formed; (b) = 1.5% of coke.

The above results, all of which refer to a single treatment of the oil vapors in the cracking zone, show that the gas yields increase rapidly with rising temperature and attain a maximum of 65 to 66 per cent by weight at 700° C. The influence of the time-temperature index on the gas yields and the olefin content of the gases is shown graphically in Figure 15 in Chapter 3. If 480° C. is taken as a standard condition the time-temperature index of cracking may be calculated from the expression $2^{\frac{T-480}{17}}t$, in which T = cracking temperature in °C., and t = contact time in minutes.

Geniesse and Reuter also reported the results of a series of recycling experiments with a gas oil, from a Seminole crude, in which the products of pyrolysis were fractionated after each cycle and the fraction corresponding to the original gas oil (boiling point 225° to 260° C.) was subjected to further pyrolysis. Liquid fractions boiling below the gas oil range were counted as gasoline and higher-boiling residues were taken arbitrarily as tar. Residues remaining in the

[59] *Ind. Eng. Chem.*, 1930, 22, 1274.

cracking apparatus were designated as coke. Recycling was repeated until the quantity of gas oil remaining was too small for further experiments. Cracking conditions were maintained constant in each stage of pyrolysis at a temperature of 600° C. and a vapor-contact time of 0.083 minute. The results of these experiments are summarized in Table 35. All yields are expressed as percentages of the charge actually fed at each separate stage of cracking.

Contrary to the experience of Cassar[60] with gasoline, Geniesse and Reuter found that yields of gaseous products from partially cracked gas oil diminish on continued cycling. Furthermore, the hydrogen content of the gas increases, partly as a result of increased coke formation.

TECHNICAL PROCESSES

By subjecting the volatile products from the distillation of solid fuel, such as raw lignite, to the lowest temperature at which pyrolytic decomposition will occur, gaseous and liquid olefins are obtained without the formation of appreciable proportions of aromatics.[61] For example, the distillates from crude lignite when treated at 300° C. yield a gas containing 60 per cent carbon dioxide and 5 to 6 per cent olefins.

A method for obtaining gases rich in olefins by passing powdered or granular bituminous coal (either mechanically or by means of a carrier such as superheated steam) through a reaction zone heated to about 800° C. has been developed.[62] This process was extended later to include substances such as tar oils, mineral oils and their distillation residues, asphalts, or the residues obtained by the destructive hydrogenation of coal, tar, or mineral oils.[63] Granular materials, such as pumice, or slag, are impregnated with these substances and then treated at red heat in the same manner as pulverized coal. The rate of decomposition may be controlled by varying the size of the granules. Afterward the granules may be re-impregnated and used again. When necessary, the carbon deposited on them can be gasified in a producer.

In another process the raw materials (bituminous coal, tars, or mineral oils) are subjected to the action of an electrically heated zone in which granular conductive materials are kept in a state of agitation by gases or hydrocarbon vapors blown through them.[64] Carbonaceous or other non-conductive substances rendered conductive by impregnation with electrolytes may be employed. If the granular material is non-bituminous, the agitation must be accomplished with hydrocarbon vapors. The reaction products are gaseous and low-boiling olefins and diolefins.

Ethylene, propylene, butylene, and amylene may be manufactured by cracking mineral oils and tars at 600° to 800° C. in the presence of gases or vapors, such as water vapor.[65] Metals, alloys, or silicates, on which difficultly reducible oxides have been deposited, can be used as catalysts. The resulting gases contain 20 to 34 per cent of ethylene, 4 to 12 per cent of propylene and 1 to 5 per cent of butylene and amylene. Curme[66] suggested an alloy catalyst, predominantly of chromium and iron, for the thermal decomposition of hydrocarbons without the aid of steam.

Eldred and Mersereau[67] obtained gases rich in olefins by exposing the vapors of petroleum distillates (particularly the fraction boiling between 150° and 200° C.) for a short time to a temperature of about 700° C. and then quickly cooling. Davis and Murray[68] proposed subjecting the vapors of gas oil to a temperature of 600° to 650° C. In still another process mineral oils are conducted through a bath of fused material (e.g., lead) maintained at a temperature of 600° C. or higher. The products can be freed of undecomposed oil, gasoline, and diolefins by cooling and compression, or by absorption, and consist of methane, ethylene, propylene and butylene. The carbon, which separates, collects on the surface of the bath.[69]

Hydrocarbons containing more than four carbon atoms per molecule can be converted at 600° C. into a mixture of olefins and diolefins by passage over catalysts consisting of difficultly reducible oxides. Cyclohexane led over calcium aluminate at this temperature is converted principally into ethylene and butadiene.[70]

An apparatus has been proposed for the production of gaseous or very volatile olefins, in which the catalyst is kept at a constant temperature by being placed in thin layers on a good heat conductor through which a cooling fluid may be circulated.[71] The hot portions of the furnace are built of metals which do not promote carbon deposition (chromium, vanadium, manganese or steel alloys containing considerable proportions of the metals of the iron group, chromium, molybdenum, tungsten, vanadium, or manganese).[72] For example, V2A steel, or iron faced with a copper-manganese bronze and lined with calcium oxide and fragments of chromium, or iron coated with a thin layer of a paste made of potassium hydroxide, potassium silicate, kieselguhr and water and silicon carbide,[73] have been suggested. It has been pointed out by Häuber[74] that elemental silicon can be used for the conversion of low-boiling olefins to high-boiling olefins by heat.

Activated charcoal, made by passing steam over brown-coal coke at 800° to 900° C., has been suggested as a catalyst for the conversion of paraffins (especially those boiling below octane) into the corresponding olefins.[75] Other proposed catalysts are the metaphosphates of the metals in Group VI,[76] and oxides, such as calcium oxide, which are not easily reduced.[77]

Light hydrocarbons, such as propane or butane, are converted at comparatively low temperature into olefins when heated in the presence of halogens or halogen-containing substances.[78] Hydrogen chloride or organic halides may be used and, in addition, metals or metallic salts as activators. Thus, by using a few hundredths of one per cent by volume of iodine with propane at 575° C., unsaturated hydrocarbons, mainly ethylene, are formed to the extent of 15.5 per cent. At 650° C., 35.3 per cent of unsaturates is obtained. Butane in the presence of carbon tetrachloride at 600° C. yields butylene (6 per cent), propylene (14.3 per cent), and ethylene (21.9 per cent).

Van Peski[79] prepared unsaturated hydrocarbons by the decomposition of saturated hydrocarbons of higher molecular weight at comparatively low temperatures in the presence of sulphur, arsenic or antimony or mixtures of these elements and their compounds. Iodine or other halogens or halogen-containing compounds may be added if desired. For example, propane at 550° C., in the presence of tellurium on pumice and a small proportion of iodine, was found to yield a mixture of gases consisting largely of ethylene.

During the pyrolysis of paraffin hydrocarbons the olefins initially formed often undergo decomposition to yield methane. However, methane formation can be materially reduced by diluting the gaseous or vaporized hydrocarbons, prior to heating, with from 1 to 9 volumes of methane.[80] The process is best carried out at 600° to 700° C. and at atmospheric, somewhat reduced, or in some instances, elevated pressures. Catalysts include the oxides of zinc, magnesium, calcium, uranium, or silver on porous substances, pumice or artificial zeolite. Thus, mixtures of ethylene, propylene and isobutylene are obtained on passing mixtures of ethane, isobutane, methane and nitrogen at 650° C. through tubes of quartz or V2A steel containing pumice mixed with zinc oxide.

Wulff[81] proposed to manufacture gaseous unsaturated hydrocarbons, including acetylene, ethylene and allylene, by pyrolysis of paraffins (ethane, casinghead gasoline, gas oil or other petroleum fractions) at temperatures above 815° C. and under a partial pressure of 75 mm. or less. Low partial pressure is attained by mixing the vaporized raw material with a diluent such as steam, mercury vapor, or nitrogen. The duration of heating should be from 0.002 to 5 seconds, after which the reaction gases are immediately cooled. Reaction is carried out in non-ferrous refractory vessels, for example, carborundum tubes containing pieces of quartz, carborundum or sillimanite. Free oxygen should be excluded.

Baths of molten salts have been suggested as heating media for the cracking of hydrocarbons.[82] Thus, butane at 750° C. passed through an equimolecular mixture of barium and calcium chlorides (which melts at 500° C.) yields a product containing 18.5 per cent propylene and 18.7 per cent ethylene. Other salt mixtures, whose melting points range from 426° to 663° C., may be employed. Molten tellurium, in aluminum-lined steel vessels, is stated to catalyze such dehydrogenation reactions.

Catalysts consisting of the heavy metals of Groups I and VIII of the Periodic Table, e.g., copper, nickel, cobalt or platinum, have been recommended.[83] When such are used the temperature range for pyrolysis is 450° to 600° C., and the time of contact should be very short (less than 2 minutes). Other catalysts which have been proposed are fire-bricks impregnated with copper salts, or bricks made from fireclay and silicon or alloys of chromium or nickel, ferro-silicon, or silicon carbide[84]; zinc, chromium, molybdenum, tungsten[85] and titanium[85a]; elemental silicon or silicon deposited on a carrier[86]; elemental silicon mixed with a binder, clay or waterglass, or deposited on silica gel,[87] as well as elemental sulphur, antimony, arsenic, selenium and tellurium.[88] Among the various heating surfaces advocated, the following are said to minimize carbon deposition: unglazed porcelain impregnated with an oxide or oxides of chromium, tungsten, vanadium or uranium[89]; chromium, tungsten or molybdenum or alloys of these metals, or graphite[90]; elemental silicon[91]; refractory materials (chamotte or silicon carbide) covered with a glaze of a silicate, phosphate or borate of an alkali or alkaline earth metal, or of copper, manganese, lead or chromium[92]; iron alloys containing 10 to 16 per cent aluminum and as high as 6 per cent chromium (Ferralloy).[93]

According to Binnie,[94] hydrogen chloride can be used as a diluent in the pyrolysis of methane and its homologues at temperatures of 1400° to 1450° C. The yield of acetylene is materially increased and the hydrogen chloride reacts but very little with the other gases present. It can be removed from the reaction products by washing with water.

Passing methane at high space velocities over a carbon catalyst at 700° to 1000° C. yields unsaturated hydrocarbons, particularly acetylene and ethylene.[95] A catalyst which is active in promoting this reaction is the lustrous graphite-like carbon deposit produced by the pyrolytic decomposition of hydrocarbons in the vapor phase in contact with lumps of clay or other refractory material. Not only methane but also its homologues may be used in producing unsaturated hydrocarbons, and dilution of the reacting gases with hydrogen is said to hinder the formation of carbon.

Wheeler, McAulay and Francis[96] proposed that in the decomposition of hydrocarbon vapors at 1000° to 1200° C. the reaction be effected in successive stages, each stage being at a higher temperature or at a lower space velocity than the preceding one. They also suggested that reaction tubes of bonded silicon carbide, bonded graphite mixture, or heat resisting alloy be used.

In the decomposition of hydrocarbons in successive stages,[97] the temperature can vary from 600° to 1000° C. in the different stages for gaseous mixtures containing very little methane, but for gases consisting mainly of methane temperatures higher than 1000° C. are necessary. As an alternative procedure the gaseous mixture is first separated into various fractions[98] and each fraction is subsequently submitted to pyrolysis under appropriate conditions of temperature.

When inert hot gases are used as direct heating media for thermal decomposition of petroleum hydrocarbons they often become contaminated with hydrogen sulphide formed by the pyrolysis of the sulphur compounds present. Before such gases can be recycled they must be freed from hydrogen sulphide. Sachs[99] effected this by washing the cooled gases with water.

SEPARATION OF THE LOWER OLEFINS FROM GAS MIXTURES

The gases obtained by the pyrolysis of hydrocarbons usually consist of complex mixtures containing, in addition to the lower monolefins, hydrogen and paraffin hydrocarbons, some butadiene and a little acetylene. The extraction of individual olefins, or mixtures of them, from the complex gaseous mixture is a problem of great importance. Both physical and chemical methods are available for this purpose. The former include such well-known processes as fractional condensation or fractional distillation of the liquefied gas mixture as well as absorption by appropriate solvents and adsorption on solid materials. The chemical methods of separation make use of differences in the chemical reactivity of the various monolefins.

SEPARATION BY LIQUEFACTION AND RECTIFICATION

One of the most promising methods of separating the various constituents of a gas mixture is fractional condensation at successively lower temperatures or higher pressures, followed by fractional distillation (if necessary) of each fraction under appropriate conditions. Alternatively, the whole gas mixture can be liquefied and the liquefied gas subjected to fractional distillation. In general, fractional condensation will not effect complete separation. Better results are usually obtained by the careful distillation of the liquefied fractions.

Although the liquefaction of normally gaseous substances is facilitated by increased pressure, there exists a critical temperature for every gas, i.e., a temperature above which no amount of pressure alone will effect liquefaction. The pressure required to convert a gas to a liquid at the critical temperature is called the critical pressure. These fundamental constants[100] for various gaseous hydrocarbons present in cracking gas, together with their melting and boiling points, are as given in Table 36.

The wide differences between the critical temperatures of ethylene and propylene are noteworthy. Thus, gaseous propylene can be liquefied (under pressures up to 45 atmospheres) at all temperatures below 92.3° C., whereas ethylene is gaseous at all temperatures above 9.7° C. A partial separation of propylene from ethylene in mixtures of these gases is therefore possible by proper adjustment of the temperature and pressure. The separation, however, will not be complete because (1) at temperatures above 9.7° C. liquid propylene exerts a high vapor pressure and consequently will be present in considerable proportions with the ethylene in the gas phase, and (2) the liquefied propylene will contain appreciable quantities of dissolved ethylene. Accordingly, complete separation can be effected only by a fractional distillation of the liquefied propylene fraction.

The rapid advances in the technic of fractionation of very volatile hydro-

TABLE 36.—*Constants for Various Gaseous Hydrocarbons Present in Cracking Gas.*

Gas	Melting Point, ° C.	Boiling Point, ° C.	Critical Temp., ° C.	Critical Pressure, Atmos.
Methane	−184°	−161.4°	−82.5°	45.8
Ethane	−172°	−88.3°	32.1°	48.8
Propane	−189.9°	−44.5°	95.6°	43
n-Butane	−135°	0.6°	153°	36
Isobutane	−145°	−10.2°	134°	37
Ethylene	−169.4°	−103.8°	9.7°	50.9
Propylene	−185.2°	−47.0°	92.3°	45
Acetylene	−81.8°	−83.6°[a]	36°	62
Allylene	−104.7°	−27.5°	128°	

[a] This is the sublimation point of acetylene at 760 mm. See McIntosh, *J. Phys. Chem.*, 1907, 11, 306; *Chem. Abs.*, 1907, 1, 1844.

carbons have been prompted largely by the development of the use of liquefied gases as fuel. This, in turn, is an outcome of efficient stabilization of volatile gasolines. The principal gaseous hydrocarbons involved in these commercial developments are propane and the butanes, but the same procedure with certain modifications can be applied to both higher and lower boiling hydrocarbons. Progress made in the practical rectification of such volatile hydrocarbons has been described by Carney.[101] He pointed out that olefins are usually separated from specially cracked material, the cracking process being such as to yield a product containing a large proportion of the desired olefin. Ethylene was the first olefin so manufactured and probably is still the one produced in the greatest quantity. Later propylene, butylenes, and amylenes, in varying degrees of purity, were separated from cracked gases and liquids. Such separations, of course, become more difficult as the molecular weight of the olefin, as well as the number of isomers, increase. Carney further reported that it is possible, for example, to separate 90 per cent butylene[101a] (a mixture of n- and iso-butylene) by fractionation of an iso- and n-butane fraction, or to vary the content of the more reactive butylene, isobutylene, from 5 per cent to more than 80 per cent in a fraction containing only hydrocarbons of four carbon atoms.

Fractionation methods under the proper operating conditions usually yield the olefin mixed with some of the corresponding paraffin. Separation of the olefin from its paraffin analogue can be accomplished by methods described below. For many purposes such separation is unnecessary and the paraffin-olefin mixture may be utilized directly for the preparation of various derivatives of its olefin constituent.

The process of Linde-Bronn, which has been applied in Germany and Belgium to the separation of the constituents of coke-oven gas, is of interest as illustrating the potentialities of low-temperature fractionation. It has been described by Bronn[102] and consists in cooling the coke-oven gas under pressure to separate first certain easily liquefiable impurities and later an ethylene-methane condensate. In this liquefaction step the coke-oven gas is cooled in a bath of liquid air or liquid nitrogen. Fractionation of the ethylene-methane condensate yields practically pure ethylene. Complete separation of methane and of carbon monoxide from the accompanying hydrogen can be accomplished by cooling the coke-oven gas, after removal of the ethylene-methane mixture, to a temperature of about —209° C. under 10 atmospheres pressure. This low temperature is secured with liquid nitrogen maintained under reduced pressure.

---

Although most fractionations are carried out at constant pressure and at varying temperatures, a second method, namely, fractionation of the liquefied mixture at a constant temperature and gradually diminishing pressure, is also available. This process of "isothermal vaporization" has been used by Markovich and Pigulevski[103] for effecting a partial separation of the constituents of a liquefied cracking gas. This gas, produced in a semi-commercial vapor phase cracking unit operated at 580° to 620° C., was first liquefied at 100 atmospheres pressure at room temperature and then submitted to a slow, approximately isothermal vaporization. The analysis of this gas is given in Table 29 of Chapter 3.

Blanchet[104] devised a process for separating the constituents of cracking gas by fractional condensation. The crude gas from the cracking operation, whether oil-washed or not, is subjected to a temperature of about 5° C. under 2 to 5 atmospheres pressure. This removes any uncondensed pentanes and amylenes, which normally boil in the neighborhood of 35° C. The residual gases are further cooled to about 0° C. under 10 to 20 atmospheres. The butanes and butylenes are thus liquefied and withdrawn. The residual gas, containing ethylene, propylene, saturated hydrocarbons and hydrogen, is either subjected to a further cooling at higher pressures to effect liquefaction of the propylene, or is used directly for the preparation of mixtures of derivatives of ethylene and propylene.

According to Matthews and Bliss,[105] it is advantageous to fractionate unsaturated hydrocarbons in such a manner that all of the compounds in one fraction contain the same number of carbon atoms. The olefin in each fraction is then chlorinated to yield the corresponding dichloride.

By chilling cracking gas under a pressure of 100 to 120 pounds per square inch, Eldred and Mersereau[106] removed propylene and butylene as liquids, leaving ethylene and ethane in the gaseous condition. They stated, moreover, that ordinarily it is not practicable to condense ethylene and ethane by the application of high pressure and intense refrigeration, since ethylene is more easily separated in other ways, as for instance, by absorption.

Substantially pure propylene has been obtained from cracking gas in the following manner by Saunders.[107] The gas is first compressed under 100 atmospheres pressure to yield a liquid consisting of paraffins and higher olefins (butylene and amylene), together with some propylene and ethylene. By refrigerating and mixing the uncondensed gas with the liquid condensate under pressure, the propylene and ethylene present in the gas may be largely condensed to a liquid. The resulting liquid mixture is introduced under 15 to 20 atmospheres pressure into a fractionating column. The temperature of the lower end of this column is maintained at about 80° C. and that of the upper end at about 10° C. The gaseous products of this fractionation, containing a high percentage of both ethylene and propylene, are passed directly into a second similar column

under the same pressure. The temperature limits in this latter step, however, vary from about 0° C. at the bottom to about —70° C. at the top of the column. Propylene separates in liquid form at the bottom of the apparatus. From the uncondensed gases passing off at the top, ethylene may be recovered by compression to 100 atmospheres and introducing the compressed gas into a third column maintained at a temperature of about —40° C. at the bottom and —65° C. at the top. Under these circumstances the ethylene separates (together with ethane) as a liquid at the bottom of this column.

As an alternative procedure, Saunders suggested distillation of the liquid condensate at somewhat higher pressures (25 to 35 atmospheres instead of 15 to 20) which condenses a larger proportion of liquid propylene at the bottom of the column. This liquid propylene can be further rectified by redistilling (under 25 to 35 atmospheres pressure) with a temperature gradient in the fractionating column from 0° C. at the bottom to 80° C. at the top. Almost pure gaseous propylene is obtained.

The many other possible combinations of temperature and pressure lead to a number of variations in this method of separation. Some advantage, however, is realized by using high pressures to reduce the amount of refrigeration otherwise required.

Pressure distillation at low temperatures has been applied in other instances to the separation of gaseous hydrocarbon mixtures. For example, a mixture of methane, ethylene and propylene is first liquefied and then subjected to a two-stage rectification process. Gaseous methane is taken off leaving a liquid ethylene-propylene fraction in the still, and this is subsequently distilled to yield ethylene (gaseous) and propylene (liquid). By using a compressed methane-ethylene mixture as an auxiliary heat-exchange material it is possible to apply the heat absorbed in cooling the fractionating columns to the distillation.[108] The separation of ethylene, propylene, and butadiene from cracking gas[109] is similarly accomplished.

Another system for the extraction of ethylene from gas mixtures consists in first liquefying a portion of the mixture and then scrubbing the gases with this liquid in countercurrent. The gases should be freed from such impurities as acetylene and the oxides of nitrogen before scrubbing. The scrubbing liquid rich in ethylene is later fractionated.[110]

The partial segregation of olefins in cracking gas has been described by Davis and Murray.[111] They proposed to separate the gaseous olefins into three main fractions corresponding to (1) an amylene fraction, (2) a butylene fraction, and (3) a mixture of ethylene and propylene. Saturated hydrocarbons are mixed with the olefins and some hydrogen as well with the ethylene-propylene fraction. To secure the partial separation the cracking gas is subjected to compression, distillation, condensation, and absorption in oil. As the various olefin fractions are employed primarily in the manufacture of secondary and tertiary alcohols this process is discussed in detail in Chapters 14 and 16.

The fractional distillation of mixtures of olefin and paraffin hydrocarbons in the presence of a selective solvent was suggested by Deanesly.[112] In the distillation of a liquefied mixture of butylenes and butane better separation between the saturated hydrocarbons and the olefins is secured by the use of such solvents as anhydrous ammonia or methylamine. Young and Perkins [112a] separate diolefins, olefins and paraffins by distillation in the presence of dioxane, nitrobenzene or dichloroethane.

A combination of physical and chemical treatments is required in the exacting purification of ethylene used in anaesthesia.[113] Relatively warm ethylene is expanded from a pressure of about 100 atmospheres to condense out moisture and other impurities. The cold gas is then passed in heat-exchange relation with warm compressed ethylene and brought into contact with sulphuric acid of such concentration that higher olefins are absorbed without appreciable attack of the ethylene itself. The gas is neutralized with caustic potash solution, compressed, and dried, and again treated with sulphuric acid and neutralized. It is finally passed in heat-exchange relation with cold ethylene, and collected at a pressure less than that from which it was initially expanded.

SEPARATION OF OLEFINS BY THE USE OF ABSORBING LIQUIDS

A partial separation of the various lower olefins from one another, and from the corresponding paraffins, can be effected by taking advantage of the difference in their solubility in various liquid solvents. The dissolved gases can be liberated from solution by heating. Generally, the solubility of the olefins in neutral solvents increases with increasing molecular weight and, possibly on account of their greater reactivity, they are usually more soluble than the corresponding paraffins. Two types of solvents have been suggested: (1) certain organic solvents such as mineral oils or acetone in which the higher olefins are preferentially soluble, but which also tend to absorb relatively large proportions of the paraffins, and (2) certain solvents which dissolve the gaseous olefins by forming loosely bound addition compounds, but which do not dissolve saturated hydrocarbons. Solvents of this kind include aqueous solutions of metallic salts having an affinity for olefins, liquid sulphur dioxide and other similarly reactive solvents.

According to Podbielniak,[114] the extraction of ethylene from crude cracking gas can be accomplished by introducing the gas, under 400 to 500 pounds pressure, into a refrigerated fractionating column from which ethylene and some ethane are removed at the top, and propylene and heavier hydrocarbons at the bottom. Substantially pure ethylene may also be obtained by scrubbing the cracking gas with a solvent which absorbs ethylene, some of the heavier hydrocarbons and a small proportion of the methane. The ethylene and gaseous hydrocarbons are subsequently recovered from the enriched solvent by distillation. Almost pure ethylene is recovered from this distillate by pressure fractionation in a refrigerated column.

Curme [115] suggested countercurrent washing of gas mixtures, previously compressed so that the ethylene partial pressure amounts to several atmospheres, with an organic solvent such as acetone. The ethylene escapes from the wash liquid on releasing the pressure and may be further purified by distillation. If

propylene and other unsaturated hydrocarbons are present in the initial mixture they are dissolved and must be separated from the ethylene by a subsequent treatment. One process for accomplishing this consists in passing the gaseous mixture through absorption towers in contact with a cold petroleum oil, such as kerosene,[116] capable of absorbing propylene and the higher olefins without dissolving appreciable amounts of ethylene.

Ethyl alcohol [117] has also been used as a selective absorption solvent for olefins. Gases containing them are scrubbed under pressure with the alcohol, the solution passed into a flash tower and the olefin gases collected after scrubbing with water. The absorbing liquids may be distilled to recover the solvent.

Gas naphtha, a liquid recovered from the compression of cracked oil gas, has been suggested by Eldred [118] as an absorption medium since it dissolves propylene more readily than ethylene, which in turn is more easily absorbed than saturated hydrocarbons. Absorption of the gaseous olefins in this liquid is generally carried out under about 150 pounds pressure. Davis and Murray,[119] however, have shown that gas oil is a better solvent for the higher olefins, butylenes and amylenes, than for the lower ones, propylene and ethylene.

Aqueous solutions of silver, cuprous and mercury [120] salts are known to dissolve the gaseous olefins readily, probably by forming complex compounds. The olefins can be recovered from these solutions by warming or by reducing the pressure. There appear to be no published experimental data on the application of this method to the separation of individual olefins, although it is probable that all the olefins in a gaseous mixture are absorbed together. Horsley [121] recommended scrubbing coal gas with an acid solution of silver nitrate under ordinary or increased pressures at 0° to 10° C. to remove ethylene and other olefins, which may be recovered by heating the solution to 50° to 70° C., with or without reduction in pressure. An ammoniacal solution of a cuprous salt was suggested by Gordon and Hughes [122] for absorbing olefins (mainly ethylene) and carbon monoxide from coal gas, coke oven gas and similar gases under 150 to 250 atmospheres pressure. The gases released from the ammoniacal solution may be scrubbed with a solution of silver nitrate to absorb olefins and carbon monoxide. Anthes [123] proposed an ammoniacal solution of cuprous formate and separated any carbon monoxide simultaneously dissolved from the liberated olefins by preferential oxidation.

Plauson [124] has found that acetone will readily dissolve large volumes of sulphur dioxide and the resulting acetone-sulphur dioxide solution may be employed for the preferential solution of unsaturated hydrocarbons, particularly the diolefins.

For separating saturated and unsaturated liquid hydrocarbons, Johansen[125] utilized a dilute soap solution. Unsaturated hydrocarbons are more readily emulsified by such solutions and can be almost completely removed by careful adjustment of its concentration.

Ammonia has been suggested by Deanesly[125a] for the separation of butylene from butane.

SEPARATION OF OLEFINS BY ADSORPTION

Olefins can be preferentially adsorbed from gaseous mixtures of hydrocarbons on active charcoal,[126] silica gel, Florida or fuller's earth,[127] or other highly adsorptive materials, and subsequently recovered by heating the adsorbent, with or without the aid of superheated steam.[127a] The olefins appear to be much more readily adsorbed than the corresponding paraffins, and methane and hydrogen are adsorbed to only a small extent. Olefins of higher molecular weight are more easily adsorbed than ethylene, and hence this method allows ethylene to be separated from its homologues.[128] This method has been particularly recommended for the recovery of ethylene from mixtures, such as coal gas, containing relatively small initial concentrations.[129] In removing ethylene and methane from gaseous mixtures with activated charcoal at —60° C. (described by Behrens[130]) ethylene is adsorbed almost exclusively and may be recovered from the charcoal by heating to 150° to 225° C.

According to Harris,[131] the adsorbent used in separating individual olefins must first be saturated with a vapor or gas having an affinity for the adsorbent intermediate between those of the olefins to be adsorbed. For example, propylene may be separated from ethylene by passing the mixture over activated carbon saturated with water vapor.

Another process is the adsorption of olefins under pressure. Thus, the gases obtained by the treatment of hydrocarbons in the electric arc are conducted over charcoal under a pressure of 20 atmospheres to remove the acetylene.[132]

CHEMICAL SEPARATION OF OLEFINS

Perhaps the most obvious method for the separation of olefins from gaseous mixtures is absorption in a reagent capable of combining more readily with the olefins than with the other hydrocarbons present. Such methods include direct hydration, esterification with sulphuric acid or with the hydrogen halides, formation of chloro- and bromo-hydrins, direct halogenation,[133] and selective polymerization. These reactions are discussed in detail in other chapters[134] so that only very brief mention of some of them need be made here.

Direct esterification with hydrogen chloride, in both the liquid and gas phases, has been described. For example, a vapor phase cracking gas mixture containing 6 per cent butylenes, 17 per cent propylene, 27 per cent ethylene and 50 per cent methane is passed with the requisite amount of dry hydrogen chloride at 15° C. over a contact material consisting essentially of anhydrous ferric chloride.[135] On cooling to —60° C. butyl and propyl chlorides are condensed and the residual gas consists of 30 per cent ethylene and 70 per cent methane. Coffin, Sutherland and Maass[136] reported that the rates of reaction of anhydrous hydrogen chloride with the three butylenes differ so greatly that it is possible to use this reaction to separate the isomers. Thus, isobutylene is converted into the tertiary chloride at —78.5° C., but the other isomers are unaffected. Similarly, the work of Piotrowski and Winkler[137] indicates that, in the catalytic reaction of various amylenes with hydrogen chloride in the gas phase, low temperatures favor the formation of tertiary chlorides. Davis[138] suggested cold aqueous hydrochloric acid for the separation of liquid secondary and tertiary olefins. The latter react with the acid to give tertiary chlorohydrocarbons, which are removed from the unaffected secondary olefins by fractional distillation.

The numerous investigations of the reactions between sulphuric acid and olefins may be summarized briefly in the following manner. At ordinary temperatures, isobutylene and isoamylenes are absorbed in 60 per cent acid; the straight-chain amylenes and butylenes in 75 to 83 per cent acid; propylene, in acid of about 93 per cent concentration; and ethylene, only in 100 per cent acid at higher temperatures, 80° to 100° C.

A number of catalysts has been proposed for the separation of olefins by polymerization. Horsley[139] suggested conducting the gaseous mixtures containing olefins over a catalyst of acid cadmium phosphate at 150° to 200° C. under pressures greater than atmospheric. Under these conditions the homologues of ethylene undergo polymerization to condensable hydrocarbons but the ethylene passes on unchanged. According to Michel[140] when the gas mixture is led through a suspension of aluminum chloride in an inert solvent (e.g., decalin) at atmospheric or reduced pressures, the ethylene homologues are polymerized while ethylene escapes in a substantially pure condition.

PRODUCTION OF HIGHER OLEFINS BY PYROLYSIS

Liquid olefins occur in considerable quantities in commercial cracked gasolines. With the possible exception of the lower-boiling members, the pentenes and hexenes, their separation in a state even approaching purity is a matter of the greatest difficulty. The highest proportions of olefinic hydrocarbons are found in gasolines made by cracking heavier hydrocarbons in the vapor phase at atmospheric, or approximately atmospheric, pressure and at temperatures of the order of 600° C. The olefin content of cracked gasolines increases with rising cracking temperatures to a maximum and thereafter declines as a result of decomposition and polymerization. The application of pressure does not favor maximum production of olefins. In addition to acyclic olefins, cracked gasolines may contain appreciable amounts of diolefins and cyclic unsaturated hydrocarbons.

The influence of both time and temperature on the degree of unsaturation of the gasoline (end point, about 225° C.) made by cracking a Mid-Continent gas oil in the vapor phase in pyrex tubes has been investigated by Geniesse and Reuter,[141] who combined these two factors into a time-temperature index.[142] Their results, some of which are shown in Table 37, show that within the temperature range of 500° to 640° C., the iodine values of the cracked gasolines increase rapidly with rising time-temperature indices to a maximum of about 175 for a time-temperature index of about 10 and then gradually decrease (see Fig. 16).

FIG. 16.—Relation between Time-Temperature Index of Cracking and Unsaturation. (Geniesse and Reuter.)

Higher olefins are obtained not only by thermal degradation of saturated hydrocarbons of higher molecular weight but also by polymerization of olefins of lower molecular weight. The thermal synthesis of higher olefins from lower members of the series is discussed more fully in Chapter 26. It may be noted, however, that in the controlled pyrolysis of the lower olefins not only higher olefins but also saturated acyclic and cyclic hydrocarbons are produced and it is difficult to stop polymerization at any desired stage. In relatively few instances only is it possible to effect the conversion of lower olefins into higher olefins without the simultaneous formation of comparatively large proportions of other hydrocarbons. Under carefully controlled conditions the partial conversion of ethylene into butylene appears possible, and Lenher[143] has found that the oxygen-

activated polymerization of ethylene can yield large amounts of propylene, besides other substances. The use of certain catalysts at comparatively low temperatures also renders possible the synthesis of higher olefins from lower members of the series.

PRODUCTION OF STYRENE AND ITS HOMOLOGUES BY PYROLYSIS

It has long been known that styrene is formed during the pyrolysis of coal and mineral oils. This hydrocarbon and its homologues have been found to be promising materials for the manufacture of other substances, particularly resins, to which they may be readily polymerized. The primary materials generally used in making styrenes by pyrolysis are ethylbenzene and its homologues. Thus, in the process described by Mark and Wulff,[144] benzene homologues containing at least one ethyl radical are catalytically dehydrogenated in the vapor phase at temperatures of 500° to 800° C. in the presence of an inert gaseous diluent such as steam, nitrogen, or carbon dioxide. Catalysts of the reaction include metallic compounds, particularly oxides and sulphides, which are nonreducible or only partially reducible under the working conditions, for example, the oxides of calcium, lithium, strontium, magnesium, beryllium, zirconium, tungsten, molybdenum or uranium; compounds such as chromium phosphate, calcium aluminate, magnesium chromate and calcium phosphate; anthracite, active carbon, silica gel, and clay; and mixtures of these substances with each other. The addition of 1 to 3 per cent of reducible metallic compounds, copper or iron oxides, frequently increases the catalytic activity. Pretreatment of the catalyst at 300° to 600° C. with gases free from carbon, such as hydrogen, steam, nitrogen or ammonia, is said to be advantageous in promoting its life and activity. This method of operation produces styrene from ethylbenzene and methylstyrene from ethyltoluene.

Smith[145] suggested the preparation of styrenes by heating an alkylbenzene and benzene to 600° to 750° C. in the presence of substances capable of forming stable compounds with the liberated hydrogen (sulphur or a mixture of sulphur and ethylene dichloride).

Halogenated alkylbenzenes, such as chloroethylbenzene, may serve as the starting material. Thus, Smith and Jargstorff[146] made styrene by heating the halogenated hydrocarbon with a small quantity of the reaction product of pyridine, dibenzylamine, or aniline and hydrochloric, sulphuric or phosphoric acid. In other processes the halogenated alkylbenzene is heated in the presence of nonvolatile inorganic acids, such as sulphuric or phosphoric acid,[147] or in the presence of inorganic catalysts (mercurous, mercuric or zinc chlorides, mercuric oxide, sulphate or acetate).[148] As still another alternative, chloroethylbenzene is heated with an organic base (e.g., pyridine) to temperatures of 100° to 230° C. under pressures not exceeding 1 atmosphere.[149]

Aromatic hydrocarbons with unsaturated side chains may be prepared by the thermal dehydrogenation of the vapors of aromatic hydrocarbons having at least one saturated side chain of two or more carbon atoms at 450° to 700° C. under partial pressures less than atmospheric in the presence of such catalysts as oxides of cerium or zinc.[150] In this way styrene and vinylnaphthalene may be made from ethylbenzene and ethylnaphthalene, respectively.

Laage[150a] suggested the production of styrene by heating methylphenylcarbinol with a dehydrating catalyst.

ACETYLENE

Acetylene is one of the products of the pyrolysis of hydrocarbons at temperatures above 800° C. Below this temperature, however, it is formed in only small proportions. At the very high temperatures of the electric arc, high yields of acetylene are secured in the pyrolysis of all hydrocarbons.[151]

Acetylene is the only hydrocarbon known whose thermodynamic stability increases with rising temperature, but it is doubtful whether it ever becomes perfectly stable with respect to its elements. The boiling points of acetylene and some of its homologues are given in Table 38.

The occurrence of acetylene in the gases from high-temperature cracking (where temperatures range from 400° to 700° C.) has been recorded by several workers but the amounts actually present are, in all probability, very small. Though acetylene has been noted in small quantities among the products of the thermal decomposition of a number of hydrocarbons, particularly ethylene, ethane and paraffins of relatively low molecular weight, most of the work in this connection is concerned with the conversion of methane into acetylene. This interest in the formation of acetylene from methane is, no doubt, actuated by the fact that methane occurs in abundance in natural gas, coke-oven gas, and other gases, and its more efficient utilization is a problem of increasing importance.[152]

[a] International Critical Tables, National Research Council, McGraw-Hill Book Co., New York, 1926.

The work of Fischer[153] and Stanley and Nash[154] showed that acetylene is formed by the thermal decomposition of methane in the region of 1000° to 1200° C. provided the heating period is sufficiently brief. Ethylene, butadiene and aromatic hydrocarbons are obtained in addition to acetylene. In all probability, they state, the acetylene first formed is to be regarded as the intermediate in the synthesis of aromatic hydrocarbons.

Fischer and Pichler[155] studied the synthesis of acetylene from methane with reference to the equilibrium with benzene. At atmospheric pressure, time of contact 0.016 second and 1300° C., 60 grams of benzene and 75 grams of acetylene per cubic meter of methane were produced. Above 1400° C. only acetylene was obtained. A coke-oven gas, which contained 25 per cent methane, with time of contact 0.004 second at 1600° C. gave 75 per cent conversion of methane to acetylene. The yield of benzene from this gas was found to be small both at this and lower temperatures. Under reduced pressure (50 to 70 mm.) the yield of acetylene was 70 to 80 per cent, and that of the benzene fell as the pressure was reduced. The results conformed to the calculated equilibrium for the reaction $3C_2H_2 \rightleftarrows C_6H_6$.

When working at temperatures of 1600° to 2100° C. and using heating times varying from 0.03 to 75 seconds, Dubois[156] noted that methane yielded both acetylene and ethylene. The yield of acetylene, however, increased with increasing temperature and decreasing time of contact. Besides acetylene and ethylene, carbon black was obtained in considerable quantities. Under best conditions about 29 per cent of the methane was converted to unsaturated hydrocarbons, and the residual gas contained about 60 per cent hydrogen and 23 per cent methane.

The thermal decomposition of methane to acetylene was studied by Peters and Meyer.[157] By subjecting methane to temperatures of 1600° to 3000° C. in the presence of tungsten or carbon heating elements for extremely short intervals of time (as low as 0.0001 second) they secured excellent yields (as high as 65 per cent conversion) of acetylene, practically free from other hydrocarbons, except unchanged methane.[158]

The pyrolysis of methane in quartz tubes at temperatures of 1150° C. under pressures from atmospheric down to 25 mm. was investigated by Frolich, White and Dayton.[159] They too found it necessary to employ exceedingly short heating periods to avoid further decomposition of the acetylene initially formed. Heating for only 0.06 second at 1150° C. converted about 11 per cent of the methane to acetylene in the exit gas, and a reduction in pressure below atmospheric did not materially affect the conversion. When methane was cracked in an electric arc, acetylene was produced accompanied, however, by the deposition of large amounts of carbon. Dilution of the methane with hydrogen increased the yield of acetylene and reduced carbon formation. With methane and hydrogen in the ratio of approximately 1:2, as much as 51 per cent of the methane was converted to acetylene in one passage of the gas through the arc.[160] Biedermann and de Rudder[161] studied the pyrolysis of methane at 900° to 1500° C. and at pressures from 20 mm. to 760 mm. There was no appreciable decomposition below 1000° C., but ethylene formation was at a maximum at 1200° C. and 100 mm. Conversion to acetylene increased rapidly with rising temperature and at 1500° C. and 40 mm. the acetylene content of the reaction gas was 15 per cent (58 per cent of theoretical). Acetylene formation was always accompanied by the deposition of some carbon and it was also noted that hydrogen chloride, silica, thorium and nickel do not catalyze the decomposition of methane.

[158] The work of Peters and Fischer and their collaborators on the production of acetylene from methane at temperatures of the electric arc is discussed more fully in Chapter 9.

Dehydrogenation of ethylene to acetylene depends upon high temperature, a controlled brief time of heating, low pressure and dilution with hydrogen.[162] Without the addition of hydrogen and at atmospheric pressure, there was a maximum production (15 per cent) of acetylene at 1200° C. using a tube 3 mm. in diameter and rate of gas supply of 60 liters per hour; increasing the temperature caused separation of carbon. Dilution of the initial gas with hydrogen combined with a shorter time of heating decreased the formation of carbon and increased the yield of acetylene to 70 per cent. Oxygen added to the ethylene-hydrogen mixture did not improve the yield of acetylene. Ninety per cent conversion was effected when ethylene, either alone or diluted with hydrogen, was heated for very short periods of time to 1300° to 1400° C. under reduced pressure. At 1000° C. and 0.1 atmosphere, ethane was dehydrogenated to ethylene; at higher temperatures the main product was acetylene.

Fischer and Pichler[163] investigated the possibilities of using benzines and other petroleum distillates for the production of acetylene. They found that the yield of acetylene was very small when a benzine (boiling at 80° to 140° C.) was passed through a heated tube at 800° to 900° C. Larger yields were obtained at a lower pressure (about 0.1 atmosphere) and higher temperature. The deposition of carbon was reduced by dilution with hydrogen. At 1200° C., benzine diluted with hydrogen gave a 50 per cent yield of acetylene. The yield of acetylene was lower when a petroleum distillate (boiling from 180° to 250° C.) was thermally decomposed under similar conditions.

It is therefore evident that to produce good yields of acetylene from methane or other gaseous hydrocarbons it is necessary to apply as high temperatures as possible for very short periods. Somewhat reduced pressure and the addition of steam or hydrogen to the reacting gases tend to minimize decomposition of the hydrocarbons into carbon and hydrogen and thus assist in their conversion to acetylene.

Binnie and Wheeler[164] observed that the introduction of methane into the zone of reaction between hydrogen and chlorine made the energy of formation of hydrogen chloride available to energize the transformation of methane into acetylene. Under optimum conditions this permitted conversion of as much as 27 per cent of the methane into acetylene.

TECHNICAL METHODS FOR PRODUCING ACETYLENE

Knapp[165] described the preparation of acetylene from natural gas by passing the latter through a bed of incandescent carbon (air is excluded) maintained at a temperature higher than that attained by combustion. It is stated that a temperature of 2000° to 3500° C. is required and that the carbon reacts with the methane of the natural gas to yield acetylene:

$$CH_4 + 3C \longrightarrow 2C_2H_2.$$

Both ethylene and acetylene may be obtained by conducting methane under pressure at temperatures of 700° to 1000° C., or even higher, over a catalyst consisting of the alkaline-earth metal salts, silica, carbon, or the oxides of magnesium or beryllium, chromium, tungsten, vanadium or uranium,[166] or compounds of selenium, tellurium, or thallium.[167] Acetylene is the main product at high temperatures, if the gaseous products are quickly removed from the reaction zone. The production of acetylene by the pyrolysis of methane at 950° to 2000° C. and absolute or partial pressures of methane varying from 760 mm. at 950° to 25 mm. at 2000° C. has also been suggested.[167a]

An apparatus for effecting the cracking of methane to acetylene, or the pyrolysis of other hydrocarbon gases, has been described by Mittasch, Frankenburger and Wietzel.[168] The hydrocarbons are passed, alone or diluted with other gases, through a thin zone of high temperature which extends across substantially the whole cross-sectional area of a tube in the apparatus. A tungsten wire gauze carrying platinized asbestos in a thin layer or a highly porous refractory material such as "Marquardt composition" may be used as a catalyst.

Natural gas or gases produced during hydrogenation processes can be first converted by pyrolysis, at least partially, to liquid hydrocarbons, which are removed and the gaseous residue, either alone or mixed with other gaseous hydrocarbons, is cracked in an electric arc to yield acetylene.[169] Wulff[170] obtained acetylene by heating natural or manufactured gas to a temperature above 815° C. and quickly cooling the products of the reaction. To obtain the high temperatures necessary for the formation of acetylene from methane, Wulff[170a] burned an oxidizable gas within the interstices of a porous refractory material, which was subsequently heated electrically until the desired temperature was reached. The methane was then passed through the preheated porous material.

Acetylene may be made by passing methane, preheated to 850° C., through a quartz tube in which a flame zone is fed by oxygen-delivery nozzles.[171] The temperature attained exceeds 1000° C. and the products are unaltered methane, acetylene, carbon monoxide and hydrogen. Acetylene is isolated by solution in acetone. In another method, also dependent upon incomplete combustion, methane is conducted through an iron tube lined with refractory material and oxygen is introduced through a series of nozzles so that a temperature of 1000° C. is reached. A variation is obtained by mixing combustible gases, methane, ethane, or hydrogen, with vaporized liquid hydrocarbons and rapidly heating the mixture to a high temperature by burning part of it with oxygen or gases containing oxygen.[172]

Winter, Hull and Ferguson[173] suggested the rapid passage of methane, mixed with oxygen or air, through a tube heated above 1000° C. The mixture should contain as much oxygen as possible, without becoming explosive, and pre-ignition may be prevented by placing a gauze before the reaction zone. By raising the temperature and selecting an optimum velocity, a maximum yield of about 10 per cent of acetylene is possible.

Wheeler and McAulay[174] have proposed heating unsaturated hydrocarbons to 1100° C. at a space velocity greater than 3000 reciprocal seconds. By heating ethylene, for example, to this temperature at a space velocity of 6400 reciprocal minutes, 30 per cent of the hydrocarbon is converted to a light oil and the reaction gas contains 8 per cent of acetylene.

Other methods involving heating periods of short duration have been described by Ferguson,[175] Voituron,[176] and Binnie.[177] Ferguson converted hydrocarbon gases or vapors, with the exception of methane, into acetylene by heating with a large excess of steam to temperatures above 1000° C. for not more than 2 seconds. The treatment of saturated hydrocarbons with steam and oxygen at temperatures around 1300° C. and at high space velocities was suggested by Voituron. On the other hand, Binnie used hydrogen chloride as a diluent and carried out the pyrolysis at temperatures of 1400° to 1450° C.

Banck[178] prepared acetylene by passing a preheated mixture of methane and an inert gas over an extensive surface of porous carbon electrically heated to 1400° to 2000° C. The pyrolysis of methane at temperatures of 950° to 2000° C. and at absolute or partial pressures of methane varying from 760 mm. at 950° C.

down to 25 mm. at 2000° C. has also been suggested.[179] The ratio of surface to volume of the cracking chamber is increased at higher temperatures, being about 10:1 at 1500° C., and a halogen or halogen compound may be employed as a catalyst.

Two-stage processes for the conversion of aliphatic into aromatic hydrocarbons, in which acetylene is formed in the first stage, have also been advocated. Thus, aliphatic hydrocarbons are heated to temperatures exceeding 1600° C. for less than 0.001 second[180] or to temperatures above 1120° C. under reduced pressure for less than 0.5 second[181] to yield gas mixtures containing acetylene. The mixtures are further heat-treated in a second stage of the process to form aromatic hydrocarbons.[182]

SEPARATION OF ACETYLENE

For separating acetylene from the gaseous products of pyrolytic reactions advantage is generally taken of the solubility of this compound in various solvents. The gas is washed either with water,[182a] or better with acetone,[183] under slightly increased pressure when solution of the acetylene in the solvent readily takes place. Various other organic solvents, suggested by Horsley and Roffey,[184] are ethers or esters boiling above 100° C., especially the esters, ethers, or ester-ethers of polyhydric alcohols. Those suggested are: glycol monoformate, mono- and di-alkyl ethers of ethylene glycol, glycerol mono- and di-acetates, glycerol mono-, di-, and tri-alkyl ethers, esters of mono- and di-alkyl ethers of glycerol, esters of phthalic acid, and ethyl lactate.

Acetylene may be washed out of gas mixtures by low-boiling liquids of the nature of the commonly used refrigerants, e.g., liquid sulphur dioxide, carbon dioxide, anhydrous ammonia, methyl chloride, and ethyl chloride.[185] Metzger suggested the separation of acetylene from other hydrocarbons by bringing the mixed gases into contact with ethyl carbonate which is said to selectively absorb acetylene.[186] Nicodemus[186a] suggested acetonitrile at —10° C. as a selective solvent for extracting acetylene from gas mixtures.

Gaseous mixtures produced by the action of the electric arc on hydrocarbons contain not only acetylene but also highly unsaturated gaseous hydrocarbons such as diacetylene, allylene and butadiene. These latter may be removed by passing the gas over heated silica gel[187] or kieselguhr, by washing with nitrobenzene, gas oil of density 0.88 or halogenated hydrocarbons,[188] or by bringing them into contact with agents such as sulphuric or phosphoric acids,[189] which polymerize the highly unsaturated hydrocarbons. Wright[190] suggested allylene and 2-butene adsorbed on silica gel for use in refrigerating systems.

Askenasy[191] used an adsorbent, such as activated charcoal, for separating acetylene from gas mixtures containing ethylene, methane, hydrogen, some nitrogen and a little acetylene. The gas is passed through the adsorbent which is afterward subjected to evacuation without heating. This releases chiefly methane and hydrogen, the acetylene being recovered by heating and further evacuation.

Acetylene may be separated from diacetylene, allylene, allene or butadiene by freezing the latter hydrocarbons out of the mixture at temperatures of —30° to —81° C.[192] To facilitate its transportation and storage, the conversion of acetylene to a solid by pressure has been proposed.[193]

DIOLEFINS

The diolefins are hydrocarbons possessing two double bonds and are typified by the examples in the aliphatic series given in Table 39.

Table 39.—*Typical Diolefins of the Aliphatic Series*

		Boiling Point[a] °C.
Propadiene (Allene)	$CH_2{=}C{=}CH_2$	—32
1,2-Butadiene (Methylallene)	$CH_2{=}C{=}CHCH_3$	19
1,3-Butadiene (Divinyl)	$CH_2{=}CHCH{=}CH_2$	—2.6
2,3-Pentadiene (sym.-Dimethylallene)	$CH_3CH{=}C{=}CHCH_3$	51
2-Methyl-1,2-butadiene (unsym. Dimethylallene)	$(CH_3)_2C{=}C{=}CH_2$	40.5
2-Methyl-1,3-butadiene (Isoprene)	$CH_2{=}C(CH_3)CH{=}CH$	34
1,3-Pentadiene (Piperylene)	$CH_3CH{=}CHCH{=}CH$	44
2,3-Dimethylbutadiene (Diisopropenyl)	$CH_2{=}C(CH_3)C(CH_3){=}CH_2$	69.6
1,5-Hexadiene (Diallyl)	$CH_2{=}CHCH_2CH_2CH{=}CH_2$	60
2,4-Hexadiene (Dipropenyl)	$CH_3CH{=}CHCH{=}CHCH_3$	82

[a] International Critical Tables, McGraw-Hill Book Co., New York, 1926.

Many carbocyclic diolefins, including a large number with a conjugated system of double bonds, are known. Little has been recorded about the occurrence of these cyclic diolefins in the products of the pyrolysis of hydrocarbons but several, particularly cyclopentadiene, have been identified in low-boiling fractions from the high-temperature carbonization of coal.

From the point of view of the organic chemist, the most interesting members of the series are those possessing a conjugated system of double bonds, such as butadiene (1,3-butadiene is usually called simply butadiene) and isoprene. This type of unsaturated linkage appears to be connected with the remarkable properties of these compounds, whose tendency to polymerize to substances of high molecular weight among which are the so-called synthetic rubbers, calls for special attention.

Although there is very little evidence of the presence of allene in the gaseous products of the cracking of hydrocarbons, considerable data are available on the occurrence of butadiene, the other diolefin which is gaseous at ordinary temperatures, among the products of thermal decomposition of all kinds of hydrocarbons and of petroleum distillates. In fact, butadiene is probably an important intermediate in the formation of cyclic, particularly aromatic, hydrocarbons in thermal processes. It occurs to the extent of about 2 per cent in the gases from commercial vapor phase cracking operations, but apparently it is formed to only a trifling extent during liquid phase cracking at lower temperatures.

Of the higher aliphatic dienes, isoprene is of most interest since it was the raw material for the first synthetic rubber-like substances. Its existence in the products of pyrolysis of hydrocarbons has been definitely shown, but the quantities of it available are certainly much smaller than of butadiene. The probable presence of another butadiene homologue, namely 1,3-pentadiene (piperylene) in a sample of cracked spirit from the Cross process was indicated by the work of Brame and Hunter.[194]

ISOPRENE

Williams[195] appears to have been the first to prepare isoprene by the dry distillation of rubber. Later, Ipatiev and von Wittorf[196] observed that trimethylethylene was also formed by this method. Hlasivetz and Hinterberger[197] and Tilden[198] produced isoprene by passing turpentine through red-hot iron tubes. Mokievski[199] found that the products of this treatment (amounting to 1.5 to 3 per cent of the turpentine) contained 50 per cent isoprene and that the remainder consisted, for the most part, of trimethylethylene. Later workers reported various yields. Harries and Neresheimer[200] obtained about 10 per cent of isoprene by decomposing turpentine, dipentene or limonene over a glowing platinum spiral. They also prepared this diolefin by the action of soda-lime on a dihalogen compound of isopentane. According to Staudinger and Klever,[201] yields as high as 60 per cent of isoprene may be secured by decomposing limonene at low pressures (4 mm.) by means of an electrically heated platinum spiral. Others have indicated that the optimum temperature for the production of isoprene by the pyrolysis of turpentine, pinene or limonene or similar materials in the presence of glass, porcelain or other contact materials lies between 450° and 700° C.[202]

According to Graul, Hanschke and Webel [203] isoprene may be prepared from isopentane obtained from petroleum or oil gas. Isopentane is chlorinated and the chloro-isopentanes are treated with lime to remove hydrogen chloride and form trimethylethylene. This substance is then converted, by the addition of halogens, into a dihalide from which hydrogen halide is again removed. In this manner substantially pure isoprene is produced.

BUTADIENE

The 1,3-butadiene has been known for many years under a number of names, such as bi- or di-vinyl, diethenyl, erythrene, pyrolylene, and vinylethylene. By the term *butadiene* is generally meant the 1,3-isomer, rather than the 1,2-isomer, as it has been studied more extensively. Berthelot [204] obtained butadiene by passing a mixture of acetylene and ethylene through a red-hot porcelain tube. It was found in illuminating gas by Caventou [205] and by Armstrong and Miller.[206] It is formed when ethylene,[207] isobutylene,[208] pentane and hexane [209] are conducted through heated tubes. The decomposition of alcohol vapors in the presence of aluminum [210] and the pyrolysis of fusel oil [211] also yield this hydrocarbon.

The almost universal appearance of butadiene in the gaseous products of pyrolysis of all types of hydrocarbon materials, at temperatures immediately below those at which aromatic hydrocarbon formation becomes marked, led to the conviction that butadiene is an important intermediate in the transformation of straight-chain hydrocarbons into aromatics.[212] The evidence for this view is largely indirect. For example, Zanetti, Suydam, and Offner [213] found that the optimum temperature for the production of butadiene (750° C.) in the pyrolysis of ethylene was coincident with the initial appearance of aromatic substances in the products. Later, however, Wheeler and Wood [214] demonstrated that butadiene condenses with olefins at cracking temperatures to yield cyclohexene and its homologues, which rapidly lose hydrogen and are converted into aromatics. The production of hydroaromatics (and from them, of aromatics) is

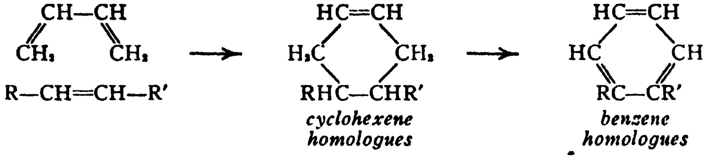
thus pictured as depending upon a condensation of butadiene with olefins. Such condensations may be represented thus:



(R and R' may be either hydrogen or alkyl groups)

As previously mentioned, butadiene has been found among the products of the pyrolysis of numerous hydrocarbons including methane, ethane, propylene, cyclohexane, and many others. It is also present in Pintsch gas, Blau gas and oil gas and in ordinary high-temperature cracking gases.[215] Systematic experiments on the production of butadiene by the pyrolysis of ethylene at various temperatures were carried out by Zanetti, Suydam and Offner,[216] who found that, with a constant heating period of 0.8 minute, the percentage yield of butadiene increased from 0.08 at 600° C. to a maximum of 0.96 at 750° C. Beyond this latter temperature the yield rapidly declined. Frolich, Simard and White[217] have determined the proportions of butadiene formed in the pyrolysis of propane, butane, ethylene, propylene and cyclohexane at atmospheric pressure and at various temperatures in an apparatus consisting of a quartz tube about 38 cm. in length and 2.5 cm. diameter. On passing propane through this tube at the rate of 27 liters per hour a maximum yield of butadiene of 0.90 mole per cent (based on propane decomposed) occurred at 727° C. Butane, using the same gas rate, gave an optimum yield of 3.12 mole per cent at 727° C. Propylene (containing 86.8 per cent of nitrogen as a diluent and passed at a rate of 20 liters per hour) gave 3.31 mole per cent of butadiene at 728° C. A single experiment with cyclohexane (41.8 cc. per hour) at 654° C. gave a very high yield of 20.60 mole per cent, based on the cyclohexane decomposed. It is evident, therefore, that the cyclohexanes are suitable starting materials for the production of butadiene by pyrolysis.

OTHER METHODS FOR THE PRODUCTION OF DIOLEFINS BY PYROLYSIS

Most of the methods for making butadiene by pyrolysis are, just as in the case of isoprene, alike in their essentials. The thermal treatment is usually carried out at temperatures ranging from approximately 450° C. to 800° C., under atmospheric or reduced pressures, and, in some instances, in the presence of various contact materials.[218] The differences between the various processes appear to be chiefly in the raw materials. In addition to the various hydrocarbons, alcohols, fats, esters and other substances have yielded butadiene on heat treatment. Of the hydrocarbons, many petroleum fractions,[219] tetrahydrobenzene,[220] cyclohexane,[221] cyclopentane,[222] dipentene or its isomers and polymerized butadiene [223] have been proposed. Various alcohols suggested include 1,3-butanediol,[224] normal and secondary butanol,[225] fusel oil,[226] many glycols [227] and cyclohexanol.[228] Olefin oxides,[229] oleic acid, and its isomers, esters, particularly fats,[230] and acetals [231] have yielded butadiene. Other methods include the polymerization of ethylene in the presence of catalysts [232] and the incomplete combustion of certain organic materials.[233] Other methods for the production of diolefins are described in Chapter 27.

Considerable interest has been manifested in the production of diolefins by the pyrolysis of petroleum. Mersereau [234] obtained diolefins from petroleum hydrocarbons (particularly those boiling above 150° C. and containing 10 to 20 carbon atoms per molecule) by subjecting them to temperatures of 600° to 800° C. The products of pyrolysis are rapidly cooled to retard further reaction and to condense oil vapors, and the condensed hydrocarbons are mixed with fresh materials and returned to the cracking chamber. The gaseous products are reported to contain 8 to 9 per cent diolefins (principally butadiene), which are separated in one of several ways, e.g., by cooling and compression, by absorption in cooled low-cold-test gas oils, or by the action of various chemical reagents such as solutions of mercuric salts or liquid sulphur dioxide. The best method of recovering the diolefins Mersereau considered to be scrubbing the gas with wash oil at about —32° C. From the cold wash oil the diolefins are released by warming and liquefied by compression and cooling. The residual gas (containing 40 to 50 per cent olefins, 4 to 5 per cent of acetylenes, and a residue of saturated gases) may be subjected to further cracking.

Bysow [235] subjected the vapors of naphtha or other fractions or residues, preheated to 300° to 400° C., to pyrolysis under reduced pressure in a short reaction zone maintained at 750° to 1000° C. in the presence of iron, nickel or aluminum catalysts. The products are cooled rapidly. The pyrolysis may be carried out also in the presence of inert gases. The unsaturated hydrocarbons so obtained are capable of polymerization to rubber-like substances.

Natural or synthetic hydrocarbons, containing more than four carbon atoms per molecule, can be converted into olefins or diolefins having a smaller number of carbon atoms by bringing their vapors at temperatures of 600° C. or higher into contact with catalysts consisting of the difficultly reducible oxides of scandium, titanium, lanthanum, tungsten, molybdenum, thorium or uranium.[236] Alternatively, vaporized paraffins, olefins or alicyclic hydrocarbons may be passed at 640° to 720° C. over lustrous carbon deposited on difficultly reducible oxides such as magnesia, lime, baryta, quartz, or metals such as chromium.[237] Thus, cyclohexane at 650° C. gives 90 per cent unsaturated olefins, chiefly butadiene and ethylene, and American petroleum at 700° to 720° C. yields 80 per cent, of which one-fifth is butadiene.

In the pyrolytic decomposition of paraffins to butadiene using silica, silicates, noble metals or the catalysts mentioned above, improved yields are obtained when the starting materials are diluted with at least half their volume of steam.[238] The best apparatus is that made of or lined with metals which do not cause deposition of carbon: chromium, vanadium, manganese, or alloys such as highly alloyed steels containing considerable proportions of chromium, nickel, vanadium, manganese, cobalt, molybdenum, or tungsten.

Various other catalysts for the decomposition of acyclic or cyclic paraffins and higher olefins to yield butadiene and isoprene have also been considered.[239] The pyrolysis is usually carried out above 600° C. and the apparatus may be constructed of refractory metals or alloyed steels (such as those just mentioned above) or of Krupp V2A steel. Iron apparatus may be used if coated with chromium, copper, graphite, aluminum, or a noble metal. Thus, the decomposition of tetrahydrobenzene and of cyclohexane can be conducted in an apparatus of this type at 650° to 700° C. in a current of nitrogen and in contact with magnesia. The metal surfaces of the apparatus may be covered also with firmly adhering melts or sinters of inorganic compounds, such as silicates, phosphates, or borates with or without further additions of chromium, manganese, or copper. The object of these various materials is to suppress carbon formation as far as possible. One volume of steam to 2 volumes of hydrocarbon may be used. For example, a mixture of cyclohexane (2 vols.) and steam (1 vol.) is passed over granular lime at 680° C. to yield butadiene, propylene and other unsaturated hydrocarbons. A 65 per cent yield of butadiene is obtained, according to Schmidt, Grosskinsky and Niemann.[240]

The production of diolefins by heating acetylene and olefin hydrocarbons together in molecular proportions for an optimum period in the presence of catalysts, such as anhydrous alkali hydroxides, has been suggested.[241] If either the pressure, time of reaction, or the temperature be increased, then polymerization products of the diolefins may be obtained in a single stage. As an illustration, a mixture of acetylene and propylene in approximately molecular proportions is forced at 3 to 15 atmospheres pressure into a thick-walled spiral tube or autoclave heated to 350° to 450° C. The spiral is provided with a check valve at the inlet and an outlet valve which can be regulated to release the gases at any desired pressure. The escaping gases are cooled and the diolefins condense. Unchanged gas is recirculated through the apparatus. By using an indifferent gas as a diluent to increase the pressure to, say, 30 atmospheres, the yield of diolefin, in the present instance isoprene, is said to be increased to 85 per cent of the theoretical. When the operation is performed in an autoclave and the heating is continued for ten to fifteen hours at 55 to 65 atmospheres pressure the diolefin undergoes polymerization to rubber-like substances and intermediate products which may be of use in varnish and as turpentine substitutes.

The indirect preparation of isoprene from acetylene by a series of reactions involving the successive synthesis of acetaldehyde, aldol, 1,3-butylene glycol, methyl ethyl ketone, 2-methyl-3-keto-butanol, 2-methyl-1,3-butylene glycol, and finally isoprene has also been described.[242] Dubosc [243] outlined a similar procedure for making butadiene, and subsequently synthetic rubber from it. The steps include the formation of acetylene (from calcium carbide), acetaldehyde, aldol, butylene glycol, and lastly butadiene.

The thermal decomposition or dehydration of the lower aliphatic alcohols to yield diolefins has been known for many years. Lebedev [244] proposed the dehydration of methyl, ethyl or propyl alcohol at 400° C. in the presence of such catalysts as alumina or zinc oxide. The products may be passed into bromine and the tetrabromide thus formed may be separated by fractional distillation and converted into butadiene by reduction The use of 1,3-butylene glycol for the preparation of butadiene has also been suggested.[245] Its dehydration is carried out by conducting the vapors of the glycol together with water vapor over heated catalysts (acid bismuth orthophosphate, neutral pyro- or orthophosphates of magnesium or the alkaline earth metals, a mixture of calcium and ammonium phosphates, or primary sodium phosphate and either graphite or phosphoric acid). By dehydration, ethylene can be obtained from ethyl alcohol, cyclohexene from cyclohexanol, and isoprene from 2-methyl-1,3-butylene glycol. Unsaturated alcohols have also been used.[246]

That lower molecular weight olefins can be condensed to those of higher molecular weight has long been known.[247] Häuber,[248] for example, suggested heating the lower olefins to 250° C. in the presence of silicon to effect the formation of higher olefins. Feiler [249] subjected the lower olefins to high-temperature electrical discharges in a closed cycle with continual removal of the products (olefins and diolefins) by cooling. Butadiene has been formed by passing a mixture of 1- and 2-butenes (obtained by the dehydration of butyl alcohol vapor at 320° C. over bauxite) diluted with nitrogen through a tube packed with calcium oxide and heated to 700° C.[249a]

It is interesting to note that butadiene may also be obtained by the partial hydrogenation of diacetylene in the presence of catalysts,[250] and by the reduction of diacetylene with chromous chloride solution.[251]

SEPARATION OF THE DIOLEFINS

For the separation of diolefins (particularly those of low molecular weight) from mixtures, use is generally made of certain materials exerting a preferential solvent action on these hydrocarbons. Sulphur dioxide is especially appropriate for this purpose, but the effect is probably not purely solvent action since compound formation undoubtedly occurs. For instance, Matthews and Elder[252] formed addition products of various olefins with sulphur dioxide and Staudinger[253] obtained monomeric solid reaction products by treating butadiene hydrocarbons with liquid sulphur dioxide at room temperature in the presence of 1 per cent hydroquinone as a stabilizing agent. A method for the separation of diolefins from hydrocarbon mixtures by the action of sulphur dioxide at 100° C. has been described by Perkins.[254] The process may be carried on continuously by constantly removing a portion of the reaction mixture and the diolefin-sulphur dioxide addition products are separated by distillation. The product obtained from 1,3-butadiene and sulphur dioxide is a crystalline solid (m.p., 65° C.) which is decomposed into its components by heating at temperatures exceeding 120° C. According to Plauson[255] acetone saturated with sulphur dioxide is an excellent reagent for diolefins and forms insoluble addition compounds. The latter can be filtered off as precipitates from which the diolefins may be regenerated by heating. The reactions of diolefins with sulphur dioxide and other reagents are discussed more fully in Chapter 27.

The use of various organic liquids as solvents for the separation of diolefins by selective solution from gaseous or liquid mixtures containing monolefins or saturated hydrocarbons has been described.[256] The liquids suggested are glycol chlorohydrin, glycol mono- and di-acetates, glycol mono-methyl ether, glycerol di- and tri-acetates, lactic acid nitrile, diethyl tartrate, furfural and aromatic bases.

Certain metallic salts in aqueous solution or suspension, as is well known, possess an affinity for diolefins as well as for monolefins. The use of cuprous and silver salts (e.g., cuprous chloride and silver nitrate) for the separation of diolefins, particularly butadiene, in gaseous mixtures has been recommended by Feiler.[257] Under certain conditions the double compound of the diolefin with the metallic salt precipitates, and from this the diolefin may be liberated by warming.

Carbon monoxide and diolefins can be removed from gaseous mixtures by absorption in a solution of cuprous chloride.[258] Hydroxylamine hydrochloride, hydroquinone, sulphites or stannous chloride may be added to such solutions to prevent oxidation of the cuprous to cupric salts. Alkali, alkaline earth or magnesium salts dissolved in water or alcohol may be used as neutral solvents. The formation of a precipitate is obviated in such solutions and the absorbed carbon monoxide and diolefins may be recovered by warming the liquid to 40° to 80° C., under reduced pressure, if necessary.

For the separation of butadiene hydrocarbons from isobutylene and similar olefins containing a tertiary carbon atom, advantage may be taken of the relatively higher rate of absorption of the latter in sulphuric acid of the proper concentration,[259] 60 to 70 per cent being recommended.[260]

Chapter 5

Production of Aromatic Hydrocarbons by Pyrolysis of Petroleum Hydrocarbons

It has long been known that aromatic hydrocarbons may be produced in quantity by subjecting other hydrocarbons to pyrolysis at fairly high temperatures. As early as 1860 the presence of aromatic hydrocarbons was demonstrated in the tar obtained as a by-product in the manufacture of oil gas by high-temperature pyrolysis of mineral oils. The aromatic hydrocarbons in coal tar, made by the high-temperature carbonization of bituminous coal, have formed the raw materials for the manufacture of a wide variety of synthetic organic substances.

The World War created a great demand for toluene for the manufacture of the explosive, trinitrotoluene (TNT), and attempts were made to augment the supply derived from coal tar by cracking petroleum hydrocarbons at high temperatures. Toward the end of the war aromatic hydrocarbons were being produced from petroleum by cracking and several processes were in operation. As has been mentioned in Chapter 1, efforts were made at the same time to obtain toluene directly from highly aromatic crude petroleums, particularly those from Borneo. Very few, if any, crude oils, however, contain sufficient toluene initially to insure the success of this operation.

After the World War, interest in the synthesis of aromatic hydrocarbons from petroleum waned considerably, but during the last few years of the decade 1920-1930 a renewal of interest in this problem was manifest. This is particularly true of processes which utilize as raw material the abundant supplies of dry natural gas, otherwise largely wasted or inefficiently used. Two circumstances have combined to focus the attention of the petroleum industry on the production of aromatic hydrocarbons from gaseous aliphatic hydrocarbons, especially from methane and its immediate homologues. One is the increasing demand for the rigorous conservation of natural gas resources. The other is the possibility of obtaining aromatic hydrocarbons (which are excellent anti-knock materials) from natural gas for blending with gasolines to increase their anti-detonating qualities. The latter particularly has aroused wide interest. In those countries dependent upon others for supplies of liquid fuels, research on the conversion of methane and other gaseous hydrocarbons present in coal gas and coke-oven gas into liquid hydrocarbons (benzene and toluene) is being vigorously pursued. This is notably true of Great Britain and Germany.

PRODUCTION OF AROMATIC HYDROCARBONS FROM PETROLEUM

The effect of temperature on the pyrolysis of petroleum distillates varies somewhat with the nature and the composition of the raw material, but in general, it can be said: (1) temperatures from 500° to about 600° C. yield principally mixtures of olefin and paraffin hydrocarbons; (2) at about 650° C. and above, diolefins are formed; and (3) at 700° C. and slightly above, aromatic hydrocarbons are produced in quantity. At higher temperatures much hydrogen, methane, carbon and highly condensed aromatic hydrocarbons are obtained.

According to Rittmann,[1] the highest yield of aromatic hydrocarbons from pyrolysis of petroleum distillates occurs in the region of 650° to 700° C. These optimum temperatures, however, are dependent to some extent upon the nature of the oil, the pressure, the size and shape of the reaction space, and the rate of oil feed (i.e., the duration of the reaction).

In the pyrolysis of most petroleum distillates (with the possible exception of those containing large proportions of cyclohexane derivatives) the production of aromatic hydrocarbons is not the primary reaction. It is now well established that the formation of olefins and diolefins precedes that of aromatics and there is much evidence to show that the diolefins of the butadiene type are the immediate precursors of aromatic hydrocarbons. It was formerly believed that acetylene was the intermediate in the formation of aromatics during cracking. Although this may be true in the re-composition of certain gaseous hydrocarbons requiring temperatures of 800° C. and over, it is doubtful whether perceptible quantities of acetylene could be formed at temperatures at which the formation of aromatic hydrocarbons is already rapid. The fact that only negligible proportions of acetylene have been noted during the pyrolysis of hydrocarbons at 700° C. and below is, of course, not conclusive evidence against the acetylene theory of aromatic formation, since acetylene might be assumed to polymerize immediately to yield aromatics. Nevertheless, thermodynamic calculations lead to the conclusion that acetylene cannot be produced in any amount at temperatures below 800° C.

According to Smolenski, Turowicz and Dobrowolski,[2] the pyrolysis of crude Baku petroleum to yield appreciable quantities of aromatic hydrocarbons requires temperatures of 680° to 720° C. Among the products obtained at these temperatures the following hydrocarbons were identified: benzene, toluene, xylenes, naphthalene and anthracene. Above 800° C. degradation to carbon, hydrogen and methane was found to be increasingly predominant.

The thermal decomposition of petroleum distillates into aromatic hydrocarbons occurs at temperatures considerably exceeding those required for ordinary cracking operations for the production of gasoline, and consequently there is always a simultaneous formation of much permanent gas and carbonaceous material. Moreover, the separation of the aromatic hydrocarbons from the products of the pyrolysis of petroleum distillates is rendered difficult by the simultaneous occurrence of olefins and diolefins having boiling points approximating those of the aromatics. As a consequence, much sulphuric acid is required to refine the crude benzene. Too high temperatures and too heavy raw materials give poor yields of benzene, and particularly of toluene and xylene. The cracking temperature, therefore, should not exceed 700° C. Even at this temperature olefins and diolefins are important constituents of the reaction products. The yields of aromatics are variously stated by different observers. Rittman gave the yields from his process as 6 to 8 per cent each of benzene and toluene, and 4 to 6 per cent of xylene.

It is questionable whether specific catalysts are of any real value in the pyrolytic formation of aromatics. At first thought it might appear that dehydrogenating catalysts would be useful in this connection, but it should be noted that aromatics are usually formed as the result of a complex series of reactions in which dehydrogenation, polymerization and ring closure (cyclicization) may be specifically distinguished. Of course, it is known that cyclohexane derivatives can be dehydrogenated to benzene derivatives in the presence of certain catalysts, particularly nickel and palladium black. However, at the comparatively high temperatures necessary to convert aliphatic hydrocarbons to aromatics such catalysts as nickel tend to increase the yield of carbon, hydrogen and methane. Thus, Ostromislensky and Burshanadse[3] showed that crude Russian petroleum, when passed over reduced nickel at 600° to 700° C., completely disintegrated to hydrogen, methane and a carbonaceous residue. Similarly, Zanetti[4] reported that the presence of nickel did not favor the formation of aromatic hydrocarbons during the pyrolysis of propane-butane mixtures. Davidson[5] found that iron, nickel and cobalt are negative catalysts for the formation of aromatics by the pyrolysis of ethane-propane mixtures and that they accelerate the reactions producing carbon and hydrogen. On the other hand, Ostromislensky and Burshanadse[6] observed that the conversion of naphtha into aromatic hydrocarbons at 700° C. is improved by the presence of a spiral of iron gauze, a yield of 10.9 per cent of benzene having been obtained as against 7.5 per cent of benzene under the same conditions without the iron. Uhde[7] suggested heating petroleum or other hydrocarbons under pressure in intimate mixture with finely divided metals to produce liquid hydrocarbons. Iron with water may be used, the iron being regenerated by the hydrogen produced.

By distilling Zistersdorf petroleum to 300° C. in the presence of 0.5 per cent of active carbon, the fraction boiling to 200° C. increased in quantity from 1.4 to 8.1 per cent and the fraction boiling to 300° C., from 11.4 per cent to 45 per cent.[7a] No further increase was obtained by redistilling this product in the presence of active carbon with or without the addition of silicon dioxide gel.

The effect of cracking a spray oil at various temperatures and at constant rates of flow was investigated by Groll.[7b] The oil consisted of 94 per cent volatile matter and boiled between 277° and 365° C. On cracking at 600° C., the product was a complex mixture of all types of hydrocarbons. From the indications, aromatic compounds are not formed at this temperature. The substances from the distillate boiling between 65° and 70° C. were hexylenes.

At 650° C. indications of aromatics first appeared. Benzene, toluene and xylene were obtained in about equal quantities, but mixed with a large amount of aliphatic hydrocarbons. The presence of hexylenes was still noticeable. At 700° C. the yield of aromatics became more predominant, with the yield of benzene exceeding that of toluene, and a smaller amount of xylene. The total yield of liquid and solid products approaches its minimum at this temperature and the residue of the tar after distillation of the gasoline consists mainly of aromatic polycyclic hydrocarbons. Many of these have aliphatic side-chains.

From 725° to 825° C. the yields are fairly constant. The only changes brought about by further increase of temperature are the gradual disappearance of aliphatic hydrocarbons and the splitting of side-chains from the alkylated aromatics.

Varying the rate of flow of oil likewise varies the composition of the product. It was found that an increase at high temperature will favor products which correspond to those formed at a lower temperature with a smaller rate of flow.

The aromatic hydrocarbons produced in these pyrolytic processes, although resulting from a series of reactions, are themselves only intermediate products in a further sequence of changes. Given a sufficiently long heating period the aromatics initially formed will be converted into other substances and finally into hydrogen, methane and coke. The attainment of this ultimate condition is reached more rapidly in the presence of such catalysts as nickel. However, when a number of reactions can occur simultaneously it is possible by a proper choice of contact materials to catalyze one at the expense of the others, and in most of these hydrocarbon reactions in which the desired product is an intermediate in a whole sequence of changes, the time factor is always of importance.

Differences in the nature of the oil subjected to pyrolysis appear to exert only a small influence on the yield of aromatic hydrocarbons, although those oils containing cyclic hydrocarbons (particularly cyclohexane derivatives) are probably somewhat more amenable to conversion. For this reason petroleum distillates containing appreciable quantities of cyclic hydrocarbons were utilized as raw materials in some of the processes for making toluene.

Weiderpass[8] has studied the conversion of Esthonian shale oil distillates into aromatic hydrocarbons by vapor-phase cracking in a tinned iron tube at 750° C. The light fraction (boiling up to 170° C.) of the products was equivalent to about 30.2 per cent of the original shale oil, or about 39.1 per cent of the products, and consisted mainly of aromatic hydrocarbons. At the same time a large proportion of permanent gas, having a calorific value of 1200 B.t.u. per cubic foot, was obtained.

The cracking of Emba crude oil in the presence of aluminum chloride was studied by Zelinskii and Mikhlin.[8a] The oil was first dehydrated by heating to 110° C. and then cracked at atmospheric pressure in the presence of 10 per cent of aluminum chloride. The yields were 48 per cent of gasoline boiling between 50° and 200° C., 15 per cent of a fraction boiling between 200° and 300° C., and 18 per cent boiling above 300° C. The gasoline fraction (50°-200° C.) contained 11 per cent of aromatic compounds. It was treated with fuming sulphuric acid to remove aromatic compounds and then subjected to catalytic dehydrogenation. The resultant material contained 8.5 per cent of aromatic compounds formed as a result of the dehydrogenation of the hydroaromatic compounds present.

Interest was aroused near the close of the World War when several processes were put into operation in the United States and elsewhere for the production of toluene and other aromatics by the pyrolysis of petroleum fractions.

In the Hall process[9] the oil under treatment is passed through a continuous coil of about 600 feet of tubing of 1 inch internal diameter at temperatures and pressures which vary according to the desired products. The oil is vaporized and the vapors attain a speed of about 5000-6000 linear feet per minute in passing through the end of the coil where the temperature is greatest. At the exit the vapors are suddenly expanded into a tube of much greater diameter and the pressure drops to atmospheric. At this point the major portion of the pyrolysis reactions occur, accompanied by some carbon deposition. The vapors next pass into a series of dephlegmators where separation into various fractions is accomplished.

When working for motor fuel a temperature of 550° to 600° C. is maintained at the exit ends of the tubes. On the other hand when operating for aromatics (for the production of which the plant can be readily adapted), the temperatures and pressures employed are necessarily higher (about 750° C. and 105 to 110 pounds per square inch, respectively). A good yield of gas of high calorific value is simultaneously produced. The Hall process is said to give a readily refined fuel containing as high as 18.5 per cent of benzene, 17.5 per cent of toluene, and about 6.0 per cent of xylenes.

The Rittman process[10] was based on investigations carried out by the United States Bureau of Mines[11] and is adapted to the manufacture of gasoline or of benzene and toluene from petroleum. As finally adopted for commercial purposes the benzene-toluene plant consisted of six furnaces each heated by gas-burners and containing 2 rows of 5 vertical reaction tubes (11½ feet long and 8 inches in diameter). Each tube was fitted with a separate oil supply and condenser. Carbon was removed by a special wiping-chain attached spirally to a rotating rod passing up through the center of each tube. For the production of aromatic hydrocarbons the temperature was about 700° C., the pressure about 150 lbs. per sq. in. and the oil was fed to each tube at the rate of 15 gallons per hour. The reactions were found to be practically independent of the nature of the oil cracked, although solvent naphthas and light oil distillates from coal tar gave the best results. The large amount of high calorific value gas produced was sufficient for the fuel requirements of the plant. The following yields from petroleum have been reported: benzene 6 to 8 per cent, toluene 6 to 8 per cent, xylenes 4 to 6 per cent, gasoline 6 to 8 per cent, creosote oil and pitch (including higher aromatic hydrocarbons) 23 to 30 per cent, carbon 3 to 5 per cent, and permanent gas 45 to 60 per cent of the original oil.

According to Lomax, Dunstan and Thole[12] the benzene-toluene fraction produced by the Rittman process contains considerable proportions of non-benzenoid hydrocarbons, unattacked by sulphuric acid, so that the preparation of TNT from the toluene fraction of the cracked product requires special methods. On the other hand, products obtained by the Hall process contain only relatively small proportions of non-aromatic hydrocarbons which are unattacked by concentrated sulphuric acid so that the direct nitration of the toluene fraction was not difficult.

Another process for making aromatic hydrocarbons from petroleum was that of the General Petroleum Corporation, by which a yield of about 6 per cent of toluene was obtained from a petroleum distillate, high in cyclic hydrocarbons, by thermal treatment under pressure. As far as is known, however, no complete account of this process has been given, but it was probably a modification of the vapor phase process developed by Washburn[13] and later acquired by the above company.[14]

PRODUCTION OF AROMATIC FROM SATURATED HYDROCARBONS

Aromatic hydrocarbons can be produced in quantity by the pyrolysis of a large variety of gaseous hydrocarbons at temperatures of 700° C. and over. It has long been known that ethylene and acetylene could be made to yield aromatic hydrocarbons by such treatment but investigations of the conversion of paraffin hydrocarbon gases, especially methane, an abundance of which occurs in natural gas, were not undertaken until much later. The possibility of converting the gaseous paraffins of natural gas into liquid aromatic hydrocarbons is of importance in connection with the conservation and more efficient utilization of that abundant material. In countries where natural gas does not occur to any extent the gaseous hydrocarbons of coal gas and coke-oven gas might be utilized for conversion into benzene and other aromatic hydrocarbons by pyrolytic processes. The aromatic liquids so produced are valuable, on account of their comparatively high antiknock values, for blending with straight-run gasolines. In the following discussion this utilization of the gaseous paraffins will be considered in some detail.

AROMATIC HYDROCARBONS FROM METHANE

The conversion of methane into aromatic liquids and gaseous hydrocarbons was effected by Fischer,[15] who worked on the assumption that by shortening the heating period and controlling the rate of cooling, methane would not be decomposed into its elements but would yield labile residues, such as $\cdot CH_3$ $:CH_2$, and $:CH$, which would polymerize to higher hydrocarbons. When methane of varying degrees of purity was passed at high gas speeds through porcelain or quartz tubes heated to 1000° to 1200° C., he obtained considerable yields of higher hydrocarbons, chiefly aromatic. The duration of heating was of great importance. When a heating period of 60 seconds was employed complete decomposition to hydrogen and carbon occurred, and he preferred a period of about ⅓ of a second. The light oil from methane contained benzene, toluene, xylenes and naphthalene, together with unsaturated hydrocarbons. The tar was a dark brown fluid containing naphthalene and higher aromatic hydrocarbons and, in addition, more or less free carbon. Silicic acid, tungsten and molybdenum did not catalyze decomposition to carbon and hydrogen but iron and graphite did.

Later, Fischer and Pichler[16] found that maximum yields of benzene were obtained at a temperature of 1300° C. with a time of contact of 0.016 second, or by conducting methane through a series of tubes maintained at 1200° C. and removing the liquid materials after each heating. Above 1400° C. acetylene was the main product.

Similar results were obtained by Stanley and Nash[17] by passing pure methane at high gas rates through silica tubes heated at 1000° to 1200° C. The solid and liquid products were not examined in great detail but the gaseous products were subjected to a special investigation by low-temperature condensation methods. The best yield of higher hydrocarbons was obtained with a temperature of 1150° C. and a heating period of about 0.6 second. Under these conditions the yield of light oil and tar totaled 11.0 per cent, calculated on the methane used, and acetylene and ethylene in the reaction gas corresponded to 8.8 per cent of the methane. The yield of light oil was 4.8 per cent or 9.2 gallon per 1,000 cubic feet of methane. The use of comparatively long heating periods tended to cause methane to decompose almost exclusively into its elements, this tendency being greatly increased by the use of catalytically active materials such as iron and nickel.

The pyrolysis of methane at temperatures up to 1050° C. in tubular reaction chambers of quartz, porcelain, copper and iron was examined by Wheeler and

[17] *J.S.C.I.*, 1929, 48, 1T.

Wood.[18] A horizontal tube of quartz at 1050° C. gave the best yields of crude oil under these conditions and the yield of benzene was about 0.2 gallon per 1000 cubic feet of methane. Quartz and copper surfaces were found not to catalyze decomposition into carbon and hydrogen, but when an iron tube was used the methane was decomposed entirely into its elements. Dilution of the methane with nitrogen had little effect on the yield of aromatic hydrocarbons but, contrary to the experience of Fischer, dilution with hydrogen decreased the yield considerably. The gaseous products of the reaction were brominated and ethylene dibromide and butadiene tetrabromide were isolated.

The results obtained by Chamberlin and Bloom[19] on the pyrolysis of natural gas are somewhat at variance with those of preceding investigators. These differences can be accounted for by the fact that Chamberlin and Bloom employed natural gases containing appreciable proportions of ethane (3.4 to 23.3 per cent). The gas was thermally treated in tubes of silica, steel, copper, iron, nickel, monel metal and clay at temperatures as high as 900° C. Aromatic hydrocarbons (principally benzene, naphthalene and anthracene), acetylene, ethylene and other olefins, were all produced at temperatures below 900° C. The yield of benzene from natural gas amounted to 27 liters per 1000 cubic feet of gas. Fused silica, clay, copper and monel metal did not catalyze the formation of carbon and hydrogen to any extent, but iron and nickel readily decomposed methane into its elements. The observation was made that while certain forms of carbon catalyzed the decomposition of methane into its elements, the carbon made from natural gas at temperatures of 450° C., or higher, selectively converts gaseous paraffins into aromatic hydrocarbons. This activity is easily destroyed by partial oxidation or by the formation of carbon-metal compounds or graphitic carbon. In agreement with the results of Wheeler and others with pure methane, Chamberlin and Bloom found that the presence of hydrogen reduces the yield of oily products and when the concentration of hydrogen is 50 to 60 per cent of the gas treated the oil yield becomes negligible.

Vysoky[20] reported that benzene is produced during the pyrolytic decomposition of methane at 800° to 850° C., and that benzene formation is not greatly affected by the partial oxidation of methane in the presence or absence of copper catalysts.

DeRudder and Biedermann[21] studied the dissociation of methane at high temperatures and reduced pressures. This investigation, though not specifically directed toward the formation of aromatic hydrocarbons, throws much light on the mechanism of decomposition. Below 1000° C., the thermal decomposition of methane yielded only minute quantities of ethylene and no acetylene. The maximum quantity of ethylene (4 per cent of the methane) was produced at 1200° C. and 100 mm. pressure, and 2.5 per cent of acetylene was simultaneously formed. At 1300° C. and 100 mm. pressure, at 1400° C. and 50 mm., and at 1500° C. and 50 mm., no ethylene was obtained but the yields of acetylene were 6.6 per cent, 10.5 per cent and 14.5 per cent, respectively. The increased formation of acetylene with rising temperature was thus clearly demonstrated. The observation was made that nickel tubes gave products similar to those secured with tubes of quartz or Marquardt porcelain. Hydrogen chloride exerted no catalytic influence.

Padovani and Magaldi[22] found that dilution of methane with hydrogen increased the yield of unsaturated hydrocarbons during high-temperature pyrolysis.

This effect was reversed at high rates of flow of the gases, an observation which would appear to reconcile the difference between Fischer's conclusions and those of Wheeler and Wood.

Waterman and his co-workers [22a] studied the thermal decomposition of paraffin wax in the presence and in the absence of hydrogen at high pressures. It was concluded that the presence of hydrogen inhibits the formation of ring compounds, only one-seventh the quantity being formed as is formed in the absence of hydrogen.

Further experiments of Wheeler and Wood [23] were directed toward the elucidation of the mechanism of the formation of higher hydrocarbons from methane. In silica tubes at 1050° C., with heating periods of the order of 0.3 second, 84 per cent of the methane consumed was converted into higher hydrocarbons. Increasing the heating period resulted in decomposing more methane into carbon and hydrogen. The use of an iron tube led to the complete decomposition of methane into its elements (the carbon formed being of a bulky gritty nature) even at comparatively low temperatures. No difference could be detected in the formation of liquid hydrocarbons from methane in chrome-iron and in silica tubes. The carbon deposited on the silica or chrome-iron tubes was lustrous and foil-like, and its accumulation did not influence the course of the reaction. Wheeler and Wood observed that a large increase in the area of silica exposed per unit volume of gas had no appreciable effect on the rate or extent of ultimate decomposition. These investigators believed that the important reactions are homogeneous and take place throughout the volume of the gas as soon as the surface reaction has been inhibited by the formation of a protective layer of adsorbed hydrogen. This hydrogen layer is apparently not formed on iron and the surface reaction (formation of carbon and hydrogen) predominates. Static experiments in a silica bulb showed that rapid initial decomposition is chiefly a surface effect which is accelerated by packing the bulb with silica and does not proceed to a true equilibrium because of a protective hydrogen layer. On the other hand, Padovani [24] considered that increasing the heating surface is of much more importance than catalytic action. He was able to prepare high grade lampblacks (together with liquid aromatic hydrocarbons) in yields of 50 per cent or more by the pyrolysis of natural gas (98 per cent methane) or coke-oven gas (about 29 per cent methane and 58 per cent hydrogen) at temperatures of 1000° to 1300° C. Pyrolysis was effected without the aid of pressure or of catalysts.

A preliminary report on the production of liquid hydrocarbons by the pyrolysis of methane in a sillimanite reaction tube at high temperatures was presented by Smith, Grandone and Rall.[25] The following hydrocarbons were identified among the products of pyrolysis: ethylene, acetylene, benzene, naphthalene, anthracene and pyrene. Unsaturated liquids boiling above and below benzene, as well as liquids and solids of very high boiling points were also formed. While the addition of hydrogen diminished the total yield of higher hydrocarbons, the percentages of ethylene and of acetylene in the gaseous products were increased by diluting the methane with either hydrogen or nitrogen. As might be expected, the presence of ethane in the initial gas increased the yield of liquid products. The highest yields from 1000 cubic feet of methane were: about 0.3 gallon of benzene or light oil; 2.5 pounds of liquid tar containing 35 per cent of naphthalene and anthracene, together with a large amount of higher hydrocarbons; and 1200 cubic feet of gas consisting of 710 cubic feet of methane, 440 cubic feet of hydrogen, and 25 cubic feet each of ethylene and acetylene.

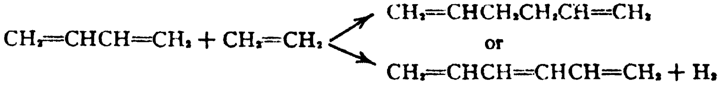
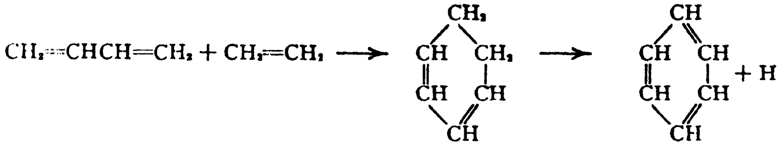
When the above results of the pyrolysis of methane are compared with corresponding ones obtained from its homologues, it is evident that methane requires much higher temperatures and produces much lower yields of liquid hydrocarbons. For these reasons, and in spite of the abundance of methane present in natural gas, it is doubtful whether the pyrolysis of methane itself to furnish motor fuels will become commercially attractive.

The formation of aromatic hydrocarbons from methane is explained by Fischer and also by Stanley and Nash by the theory of nascent radicals. Wheeler and his collaborators, however, regard the olefin hydrocarbons, and especially ethylene, as the important intermediates in the formation of aromatics. The mechanism proposed by Wheeler involves the intermediate production of the free radical $:CH_2$, two of which combine to form ethylene. Polymerization of ethylene (a well-known thermal reaction) yields butylene which in turn loses hydrogen to form 1,3-butadiene. Wheeler concluded that butadiene then reacts with more ethylene according to the following scheme:



$$CH_2{=}CHCH{=}CH_2 + CH_2{=}CH_2 \rightarrow \begin{cases} CH_2{=}CHCH_2CH_2CH{=}CH_2 \\ \text{or} \\ CH_2{=}CHCH{=}CHCH{=}CH_2 + H_2 \end{cases}$$

or



According to Hague and Wheeler,[26] ethylene fulfils all the requirements of a producer of benzene, and the theory proposed by these workers also takes into account the important rôle of diolefins, such as butadiene. Butadiene is always a product of high-temperature cracking and several prior workers, notably Davidson, arrived at the conclusion that this diolefin is a probable intermediate in the formation of aromatic hydrocarbons during pyrolysis.

The production of aromatic hydrocarbons from the homologues of methane is also easily explained on the basis of Wheeler's theory since lower olefins (especially ethylene) are always formed in quantity in the initial stages of decomposition. In the case of methane, however, some doubt has been cast on the general validity of the theory proposed by Wheeler, who appears to have ignored the considerable production of acetylene which takes place simultaneously with the formation of aromatic hydrocarbons. The formation of considerable amounts of acetylene in the region of 1050° to 1200° C. was noted by Stanley and Nash[27] and also by Frolich, White and Dayton.[28] The latter, as a result of their study of the formation of acetylene from methane by cracking under reduced pressure, concluded that acetylene is an intermediate in the production of benzene from methane. In the case of the higher paraffin hydrocarbons, which are converted into aromatics at a lower temperature than is methane, the intermediate production of acetylene is very doubtful. With the possible exception of methane, therefore, the theory of Wheeler regarding the mode of formation of aromatics during pyrolysis appears to fit the facts admirably.

AROMATIC HYDROCARBONS FROM HOMOLOGUES OF METHANE

The fact that aromatic hydrocarbons may be obtained by pyrolysis of the homologues of methane has been known for some time. In 1916, Zanetti[29] subjected the propane-butane fraction of natural gas to pyrolysis in a silica tube at various temperatures, a Cottrell separator being employed to precipitate the tar fog. It was noted that the production of unsaturated gaseous hydrocarbons attained a maximum at about 750° C. Above this temperature the formation of aromatic hydrocarbons occurred and the proportion of unsaturated hydrocarbons decreased and became practically negligible at 1000° C. The curve of hydrogen formation was found to rise slowly with increasing temperature but more rapidly during the formation of aromatics. The principal gaseous unsaturated hydrocarbon was ethylene, but the presence of propylene was suspected. Butadiene was isolated as its tetrabromide, while benzene, toluene and naphthalene were shown to be present in the tar. Catalysts were used and it was observed that copper behaved in a manner similar to silica but nickel and iron induced a marked decomposition of the gas into its elements, the iron at 725° C. and the nickel at an even lower temperature, and no tar fog was produced in either case.

The pyrolysis of the ethane-propane fraction of natural gas was examined by Zanetti and Leslie.[30] As with the propane-butane fraction, the proportion of unsaturated hydrocarbons increased with increasing temperature to a maximum at about 750° C. and then decreased. As before, the beginning of the decrease in the proportion of unsaturated hydrocarbons and the rise in hydrogen production was coincident with the appearance of a tar fog and the formation of aromatic hydrocarbons. The tar obtained by the pyrolysis of ethane-propane mixtures above 750° C. was later examined by Zanetti and Egloff[31] and benzene, toluene, naphthalene and higher aromatics were identified.

Further investigations of the formation of aromatic hydrocarbons by the pyrolysis of ethane-propane mixtures were carried out by Davidson,[32] who studied the effect of various catalysts on the progress of the decomposition. With the exception of iron, nickel and cobalt, metals do not seem to exert any great catalytic influence on the reaction nor do variations in the surface exposed appear to influence it. Iron, nickel and cobalt were found to be negative catalysts of the reaction yielding aromatic hydrocarbons, and they greatly accelerate the decomposition of the hydrocarbon gases into carbon and hydrogen. The optimum temperature for the production of aromatic hydrocarbons was found to be 850° C. Davidson further investigated the influence of pressure on the pyrolysis of ethane-propane mixtures. Up to 700° C. it was found that increasing the pressure increased the formation of unsaturated hydrocarbons and hydrogen. Above 700° C. increasing the pressure decreased the proportion of aromatic hydrocarbons. Davidson concluded from these pressure experiments that the main reaction resulting in the formation of aromatics from paraffin hydrocarbons begins at 700° C., and is accompanied by an increase in volume notwithstanding the fact that it is also a condensation reaction.

The formation of benzene and its homologues (and also of naphthalene and

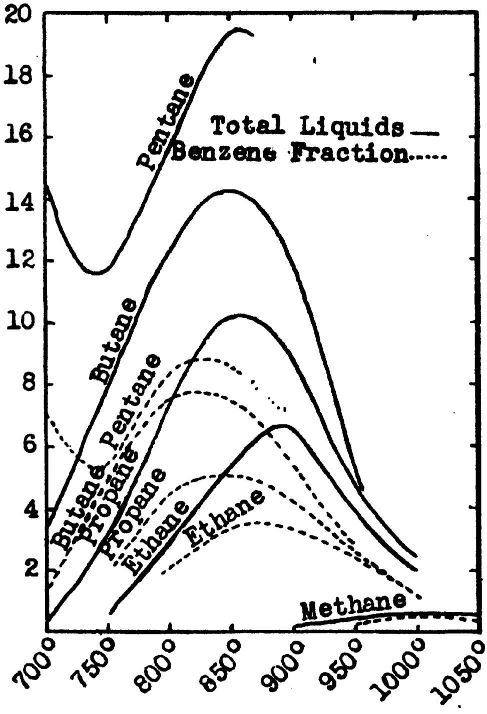
[32] *Ind. Eng. Chem.*, 1918, **10**, 901.

other polynuclear aromatic compounds) from ethane at 700° to 900° C. was observed by Williams-Gardner.[33] He ascribed the formation of aromatic hydrocarbons to the peculiar behavior of ethylene (an intermediate product) in the region of 750° C.

A comprehensive study of the conversion of the lower paraffin hydrocarbons to aromatic hydrocarbons by pyrolysis was reported by Hague and Wheeler.[34] Perhaps the most striking feature of their results is the similarity they found



Courtesy Fuel.

FIG. 17.—Pyrolysis of Paraffin Hydrocarbons. Yields, at Various Temperatures, of Total Liquids and of Benzene in Grams per Gram-Mole of Hydrocarbon. (Hague and Wheeler.)

in the behavior of all the hydrocarbons studied, methane included, at the higher temperatures. Below 750° C. and in this temperature range each hydrocarbon follows an individual course. At higher temperatures secondary reactions take place which, however, yield the same type of products in all cases. The liquid products obtained by pyrolysis below about 750° C. contained appreciable proportions of unsaturated hydrocarbons and the light benzene fraction could not be solidified in a freezing mixture. When pyrolysis was effected at temperatures above 750° C. then nearly pure benzene could be separated by fractionation of the liquid tar. The yields of liquids and the temperature ranges over which such yields were obtained are shown in Figure 17 on the preceding page, in which the yields, expressed in grams per gram-mole, are plotted against the temperature. With increasing molecular weight from ethane to pentane the yields of liquids increase in the approximate ratio 2:3:4:5. The proportion of light distillate boiling from 80° to 90° C. was usually at a maximum at a temperature slightly below that for maximum yield of liquid and varied from 11.2 per cent by weight for ethane to about 19.0 per cent for n-hexane. The optimum yield of aromatic liquids (expressed in percentage by weight of the initial hydrocarbon) and the temperatures at which they were obtained are as follows:

---

[33] *Fuel*, 1925, 4, 430.
[34] *Fuel*, 1929, 8, 512, 560.

Hydrocarbon	Temperature ° C.	Total Liquid % by Weight
Ethane	900	21.9
Propane	850	23.1
n-Butane	850	24.6
n-Pentane	850	26.8
n-Hexane	850	33.8

It should be noted that the homologues of methane give much higher yields of aromatic hydrocarbons on pyrolysis than methane itself. This point is emphasized by the results of some large-scale tests carried out by Dunstan[35] on the pyrolysis of two types of natural gas having the following percentage compositions:

Constituents	Gas I	Gas II
H_2S, O_2, and CO_2	1.6	9.7
N_2	1.4	1.7
CH_4	81.0	36.0
C_2H_6	16.0	32.0
C_3H_8	—	9.0
C_4H_{10}	—	9.0
C_6H_{12}	—	6.0

On the pyrolysis of these gases in silica tubes, gas I gave a yield of 220 gallons of benzene per 1,000,000 cubic feet, and gas II, 770 gallons of benzene and quantities of tar from the same volume of gas. It is evident, therefore, that gases comparatively rich in the homologues of methane give much higher yields of aromatic hydrocarbons than do "dry" gases consisting principally of methane itself.

The pyrolysis of ethane, propane and butanes (as well as mixtures of these) to produce aromatic oils has been the subject of an important study by Frey and Hepp,[36] who paid special attention to the time factor. The pyrolysis was carried out in silica reaction tubes heated electrically to the desired temperature, and the products of cracking were passed through an electric precipitator, where suspended tar was collected. The base of the tar precipitator was maintained at 60° C. to avoid condensation of toluene or lower-boiling components, and the gases issuing from it passed to a solid carbon dioxide-acetone bath to condense volatile liquid hydrocarbons. From the heats of formation of the reactants and the products, assuming a constant temperature of 850° C., variations in the heat content during cracking were calculated. In this manner Frey and Hepp were able to distinguish two well-defined thermal effects during the course of pyrolysis, namely, (1) a highly endothermic reaction corresponding to the formation of the maximum concentration of gaseous olefins and occurring at an exposure time of about 0.0025 minute, and (2) a marked exothermic reaction (about 190 calories per gram) corresponding to the aromatization of the gaseous olefins and developed at times of exposure of 0.0025 to 0.08 minute. In later experiments on a large scale these two distinct reactions were conducted separately. Butane was cracked at 750° to 770° C., under 2 atmospheres pressure, and then passed into an insulated chamber in which formation of aromatic hydrocarbons took place without the further introduction of heat. A temperature rise of over 50° C. was noted in the latter step. By sufficiently reducing the rate of flow (or increasing the time of contact) it was possible to obtain a temperature rise of more than 100° C.

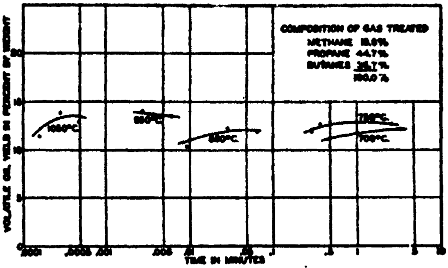
The influence of time and temperature on the production of volatile aromatic oils was investigated by Frey and Hepp using, as a raw material, a gas consisting of 18.6 per cent methane, 44.7 per cent propane, and 36.7 per cent butanes. The yields of volatile oils obtained at temperatures varying from 700° C. to 1050° C. and at times of contact from about 0.0002 to 4 minutes are shown graphically in Figure 18. The remarkable fact is thus clearly demonstrated that, within this rather wide range of temperature, the maximum yield of volatile oils was approximately constant (being equal to about 14 per cent by weight of the gas mixture) for those limits of contact appropriate for each temperature. The minimum values of contact time required to develop a roughly maximum yield of oils within this temperature range were found to be related to the operating temperature by the empirical formula:



Courtesy Industrial and Engineering Chemistry.

FIG. 18.—Effect of Time and Temperature on Yields of Volatile Oils.
(Frey and Hepp.)

$$T = 690 - 100 \log t$$

where T = temperature in ° C.
and t = contact time in minutes

The effect of the time factor on the composition of the liquid and solid products of pyrolysis (at 850° C.) of the gas mixture mentioned above is shown in Table 40.

The volatile oils produced at shorter times of contact contained a large proportion of unsaturated hydrocarbons. The oil obtained in run 6, at the long contact time of 0.40 minute, consisted almost entirely of benzene.

To obtain more detailed information about the composition of the volatile oils, large quantities of these were prepared by Frey and Hepp by the pyrolysis

(at 850° C. using different times of contact) of a gas mixture consisting of 89 per cent of n-butane and 11 per cent of isobutane. These oils were carefully examined by fractional distillation at temperatures below 15° C. in a modified column used for gas analysis. Propylene, butylene (mainly isobutylene) 1,3-butadiene, pentenes, cyclopentadiene, a hexene fraction consisting principally of hexadiene (and some methylcyclopentadiene), benzene, toluene, xylenes and styrene were found. From the results of these experiments (Table 41), it will be seen that in the early stages of benzene formation, butadiene, cyclopentadiene and other highly unsaturated hydrocarbons were present in fairly large proportions. As the time of contact is increased, however, the proportion of diolefins and of toluene decreases and benzene tends to become the main constituent of the volatile oils.

Experiments reported by Frey and Hepp on the pyrolysis of propane at a pressure of 9.5 atmospheres and a temperature of 750° C. indicated that the maximum yield of volatile oil under these conditions was about the same as that obtained at atmospheric pressure. Experiments in which different hydrocarbons were pyrolyzed under conditions giving a maximum yield of volatile oils showed that the yield of benzene and toluene increases with the carbon-hydrogen ratio in the initial hydrocarbon.

Thermal decomposition of isopentane at 680° C. in the presence of silica gel, at one atmosphere pressure and 15 seconds contact, yields about 75 per cent of gaseous and 25 per cent of liquid materials.[37] Methane, ethylene, propylene and butadiene were identified in the gases, and the liquids contained a large proportion of ethylenic and aromatic hydrocarbons.

Podbielniak[88] has given an interesting account of large-scale experiments on the cracking of various mixtures of the lower paraffins to produce aromatic liquid hydrocarbons. At the high temperatures necessary for pyrolysis it was found that the heat-resistant alloy reaction tubes rapidly failed through oxidation on the outside and extensive carbonization on the inside. Because of the disadvantages connected with non-metallic refractories, special composition high-heat resistant alloys were subsequently used. The life of the tubes was increased by (1) careful control of the furnace temperature, (2) application of radiant heat rather than convection heat to the last alloy tube passing through the furnace, (3) careful regulation of the temperature gradient in the tubes, and (4) greatly increasing the gas velocity in the tubes. By taking these steps a material improvement in the effective life of the high-temperature reaction tubes was attained, and it was concluded that in a commercial plant the life of the reaction tubes should amount to many thousand hours at the high temperatures required for the maximum production of aromatics. Podbielniak also reported that at high gas velocities the formation and deposition of carbon on the tube walls was reduced to such an extent that the tube required blowing (with superheated steam or air) only about once every 8 to 12 hours. The carbon deposit was fairly light and fluffy and a blow period of only 15 minutes was usually sufficient to clean it out. At high gas velocities, the formation of hydrogen was suppressed to a very low figure.

The crude liquid obtained by pyrolysis contained 30 to 60 per cent of benzol, 15 to 20 per cent of toluol, and a residue consisting principally of higher aromatic hydrocarbons. The exact composition of the condensates depended upon the pyrolysis temperature and the times of contact but generally from 75 to 85 per cent of the product met motor fuel specifications for boiling range when distilled in an Engler apparatus.

Podbielniak also supplied data for the cracking of gaseous paraffin hydrocarbons particularly with respect to the production of ethylene. Table 42 summarizes some of the experimental results obtained in large-scale operations.

TABLE 42.—*Yield of Ethylene from Cracking of Gaseous Paraffin Hydrocarbons.*

hydrocarbons. The latter consist largely of benzene, naphthalene and anthracene. Only a small proportion of aromatics having side chains were formed.

MECHANISM OF THE FORMATION OF AROMATIC HYDROCARBONS FROM METHANE HOMOLOGUES

It is now generally agreed that aromatic hydrocarbons are not the primary results of the pyrolysis of the lower paraffin hydrocarbons but are formed by secondary changes induced by the further action of heat on the primary decomposition products. Three principal theories of aromatic formation have been proposed. Berthelot's[40] theory assumes the intermediate to be acetylene which undergoes direct polymerization to aromatic hydrocarbons. However all the evidence of later experimental work indicates that acetylene is formed only to a very slight extent in the temperature range yielding aromatic hydrocarbons most readily. Nevertheless with methane, which required much higher temperatures than its homologues for conversion into aromatic hydrocarbons, the intermediate formation of acetylene is a distinct possibility.

A second theory[41] involves the intermediate production of a cyclohexane which loses hydrogen to become an aromatic hydrocarbon. The cycloparaffin intermediate might be derived from a paraffin in one of three ways, namely (1) by simple ring closure of an olefin of six or more carbon atoms which originates from a paraffin of the same or larger number of carbon atoms by splitting; (2) by the polymerization of an olefin with ring closure; or (3) by the intermediate formation of free radicals, such as $:CH_2$, followed by polymerization.

According to the third theory, which appears to be substantiated by experimental evidence to a greater extent than either of the others, the intermediate substances responsible for the formation of aromatic hydrocarbons are the monolefins and the diolefins, particularly butadiene. The exact details of this mechanism are yet subjects of disagreement.

Davidson[42] was apparently the first investigator to emphasize the probable importance of butadiene as an immediate precursor of aromatics. Wheeler and Hague,[43] as previously noted, suggested that benzene is produced by the direct combination of butadiene with ethylene. Butadiene is the result of the dehydrogenation of butylene, which may be formed either by the splitting of a higher paraffin or by the polymerization of ethylene molecules. Later Wheeler and Wood[44] adduced evidence to show that ethylene and butadiene combine in equimolecular proportions to produce cyclohexene, and that similar condensations of propylene or butylene with butadiene yield substituted hydroaromatic hydrocarbons. The latter rapidly lose hydrogen at the high temperatures of pyrolysis to give benzene and its homologues.

A very careful investigation of this question has been carried out by Schneider and Frolich,[45] who made a study of the initial products of the pyrolysis of propane, propylene, ethylene, and butadiene at temperatures above 700° C. with very short times of contact, i.e., low percentage cracking. According to these investigators, butadiene appears to be formed directly from ethylene, without the intermediate formation of butylene, by the reaction

$$2C_2H_4 \longrightarrow C_4H_6 + H_2$$

---

[43] *J.C.S.*, 1929, 378.

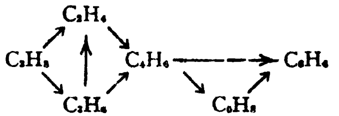
[44] *J.C.S.*, 1930, 1819.

[45] *Ind. Eng. Chem.*, 1931, **23**, 1405.

Experiments on the pyrolysis of a mixture of ethylene (90 per cent) and butadiene (10 per cent) at 725° C. and 0.2 atmosphere pressure showed clearly that the two principal primary reactions may be represented thus:

$$C_4H_6 + C_2H_4 \longrightarrow C_6H_8 + H_2$$
$$C_4H_6 + C_2H_4 \longrightarrow C_6H_6 + 2H_2$$

The data suggest that part of the benzene is formed directly while part of it originates by dehydrogenation of the intermediately formed triolefin, C_6H_8. The work of Schneider and Frolich is therefore consistent with the view of others that benzene is produced in pyrolytic processes by a combination of ethylene with butadiene either directly or through an intermediate triolefin. The reaction scheme by which another typical lower paraffin, propane, is converted into benzene is as follows:



Just as butadiene reacts with ethylene to yield benzene, so benzene undergoes further reaction to yield alkylated derivatives, naphthalene, and eventually tarry compounds of high molecular weight.

AROMATIC HYDROCARBONS FROM ETHYLENE

A number of investigators have shown clearly the possibility of producing aromatic hydrocarbons from ethylene by pyrolysis. The important function assigned to ethylene by Hague and Wheeler as an intermediate in the formation of aromatics by the thermal decomposition of paraffin hydrocarbons has already been mentioned. Ethylene appears to be fairly stable up to about 700° to 750° C. Above this temperature there is a marked tendency for this olefin to form aromatic hydrocarbons. Hague and Wheeler found that the optimum temperature for the production of liquid hydrocarbons (mainly benzene) from ethylene in the presence of silica or porcelain surfaces is 750° to 800° C. The total yield of liquid, at 800° C., represented 28.9 per cent of the ethylene passed. Dilution of the ethylene with hydrogen decreased the yield of benzene and the temperature of maximum yield was increased. The formation of liquid hydrocarbons by the non-catalytic thermal decomposition of ethylene at atmospheric or increased pressures has been investigated by Waterman and Tulleners.[46] Appreciable yields of aromatic hydrocarbons have been obtained by Mailhe and Renaudie[47] by passing ethylene over a mass of silica gel granules heated to 700° C. In addition to benzene and toluene, unsaturated hydrocarbons were present in the light fractions.

Berl and Forst[48] procured yields as high as 43 per cent of liquid products from ethylene by circulating this gas for several hours through a porcelain tube heated to 800° to 900° C. The ratio of light oils to heavy oils in the liquid condensate, which was principally aromatic, was dependent upon the temperature and the velocity of circulation. The liquids contained benzene, naphthalene, anthracene and their homologues together with a small proportion of cyclo-

[47] *Compt. rend.*, 1930, 191, 265. This work on the transformation of gaseous hydrocarbons into liquid fuels is reviewed by Mailhe (*Tech. moderne*, 1931, 23, 581, 621; *Chem. Abs.*, 1932, 26, 279).

[48] *Z. angew. Chem.*, 1931, 44, 193; *Brit. Chem. Abs.* A, 1931, 596.

pentadiene. Packing the tube with pieces of porcelain slightly increased the total yield as well as the proportion of light oil. The presence of metals, or metallic oxides, greatly reduced the formation of liquid products, presumably because of the activity of these substances in catalyzing the decomposition of ethylene into its elements.

The important influence of pressure in promoting the conversion of ethylene into liquid hydrocarbons is well known from the work of Ipatiev and others.[49] Under pressures of about 70 atmospheres, and higher, a rapid conversion of ethylene into liquid hydrocarbons (not aromatic, but principally paraffins and cycloparaffins) occurs even at temperatures as low as 350° C. Most of the work on the conversion of ethylene and its homologues into aromatic hydrocarbons has been done at temperatures of 600° C. and above and at atmospheric pressure. Increased pressure accelerates the conversion to liquid hydrocarbons, but at the same time it suppresses the formation of aromatics. Thus Frolich,[50] from his experiments with ethylene and propylene, showed that when the pressure is increased and the temperature of pyrolysis maintained constant, the proportion of hydrogen liberated becomes less and the liquid products lose more of their aromatic character until, at pressures of several thousand pounds per square inch, the liquid material obtained is decidedly non-aromatic even when the reaction temperature is as high as 600° C. The heat treatment of olefin gases under pressure to yield liquid hydrocarbons of a non-aromatic character has been investigated also by Dunstan, Hague and Wheeler.[51]

AROMATIC HYDROCARBONS FROM HOMOLOGUES OF ETHYLENE

The homologues of ethylene are similarly converted into a mixture of aromatic hydrocarbons when subjected to pyrolysis at temperatures of 600° C. and higher at atmospheric pressure. As with ethylene, the application of higher pressures tends to favor condensation to non-benzenoid liquid hydrocarbons, even at temperatures as high as 600° C. The most comprehensive investigations of the pyrolysis of the immediate homologues of ethylene are those of Wheeler and Wood [52] and Hurd and his collaborators.[53]

The yields of liquid products obtained by Wheeler and Wood in the pyrolysis of propylene in a vertical quartz tube, at atmospheric pressure and at temperatures varying from 650° to 900° C., are shown in Table 43. Analyses of the resulting gases have already been given in Table 19.

The liquids of lower boiling point, obtained at 650° C., were said to be mainly unsaturated monocyclic paraffins of the cyclohexene type, while those produced at 700° C. and higher were principally benzene and toluene. The proportions of benzene and toluene formed from propylene at 700° C. were greater than from ethylene under similar conditions.

Hurd and Meinert obtained yields of aromatic liquids, amounting to 20 to 25 per cent by weight of the propylene decomposed, by pyrolysis in pyrex or quartz tubes at 700° C. and higher. Mailhe and Renaudie[54] conducted propylene over a silica gel contact mass at 650° C. and produced a liquid condensate containing low-boiling olefins together with aromatic hydrocarbons and a tar in which toluene, m-xylene, naphthalene and anthracene were detected.

By the pyrolysis of both 1-butene and 2-butene in quartz tubes at temperatures ranging from 600° to 900° C., Wood and Wheeler secured yields of aromatic liquids as high as 40 per cent by weight of the butene employed. Table 44 summarizes the results of these investigators. Gas analyses are shown in Table 20.

Table 44.—*Pyrolysis of 1-Butene and 2-Butene.*

		Yields (Per Cent by Weight of Butene Treated)					
		From 1-Butene			From 2-Butene		
Temp. ° C.	Contact Time Secs.	Total Liquids	Distillate up to 170° C.	Carbon	Total Liquids	Distillate up to 170° C.	Carbon
600°	61.5	12.9	6.5	Nil	5.2	1.4	Nil
650°	58.2	29.8	20.3	Nil	27.0	17.2	Nil
700°	55	35.8	23.6	Trace	37.0	25.8	Trace
750°	52.5	39.6	22.4	Trace	39.6	23.2	Trace
800°	50	39.4	19.9	1.0	37.9	18.6	1.4
850°	47.7	35.0	16.2	4.7	31.6	14.2	4.7
900°	45.7	13.9	7.8	7.1	12.4	6.1	5.4

In the liquid products obtained by the decomposition of a mixture of 1-butene and 2-butene, at 600° C., cyclohexene and methylcyclohexene predominated; cyclohexadiene and methylcyclohexadiene were also present; and benzene and toluene were found only in comparatively small proportions. Only 18.5 per cent of this liquid product boiled above 117° C. On the other hand, of the liquids formed from pure 2-butene at 650° C., 29.6 per cent boiled above 110° C. and 16.6 per cent above 150° C., both fractions consisting largely of aromatic hydrocarbons.

The pyrolysis of isobutene was studied by Hurd and Spence,[55] who found that at 700° C. and a contact time of 18 seconds the yield of liquid products was about 30 per cent by weight of the isobutane used or about 63 per cent of the isobutane decomposed. By fractional distillation about one-half of this condensate was shown to be benzene and toluene. The remainder appeared to be a mixture of xylenes, naphthalene, methylnaphthalene, diphenyl, ditolyl (?), anthracene, phenanthrene, and other aromatic hydrocarbons.

Mailhe and Renaudie[56] reported the conversion of 1-butene and 2-butene into liquid hydrocarbons by passage over a contact mass of silica gel at 650° to 700° C.

From 1-butene, at a temperature 650° to 670° C., a yield of 33 per cent (by weight of the butene charged per single passage) of liquid hydrocarbons was obtained, and also methane and propylene. The liquid contained benzene, toluene, and m-xylene, totaling about 21 per cent, but neither naphthalene nor anthracene. Under the same conditions similar results were obtained with isobutylene. By heating 2-butene to 700° C. in the presence of silica gel, the yield of liquids, consisting largely of aromatic hydrocarbons, was 37.7 per cent of the weight of the butene charged. This butene differed from the other two in that it produced a tar in which both naphthalene and anthracene were found.

Ivanov [56a] found that the liquid product obtained by pyrolysis of an ethylene concentrate from cracked mineral oil consisted chiefly of benzene and olefin hydrocarbons. The gas was passed through a silica tube at 550°-580° C. under a pressure of 1 atmosphere. On raising the temperature the benzene content increased while the olefin content decreased. In the presence of zinc chloride at a temperature of 320°-360° C. and a pressure of 30 to 70 atmospheres, a maximum yield of low-boiling products was obtained which consisted of paraffin, olefin, aromatic and naphthene hydrocarbons.

AROMATIC HYDROCARBONS FROM ACETYLENE

The fact that acetylene can be converted into aromatic hydrocarbons by thermal treatment has long been known and indeed constitutes a classical synthesis of benzene and its homologues. The most favorable temperatures for conversion appear to lie within the range of 600° to 700° C. Above the higher temperature the condensation reaction is largely replaced by decomposition of acetylene to carbon and hydrogen, accompanied by hydrogenation to ethylene, ethane and methane. Extensive work on the formation of aromatic hydrocarbons from acetylene was carried out by Meyer and his collaborators,[57] who identified the following hydrocarbons among the products of pyrolysis: hexane, benzene, toluene, o-, m-, and p-xylenes, styrene, pseudocumene, mesitylene, indene, naphthalene, methylnaphthalenes, diphenyl, acenaphthene, fluorene, anthracene, pyrene, phenanthrene, fluoranthrene and chrysene.

The condensation of acetylene to liquid hydrocarbons has been investigated by Fischer, Bangert and Pichler,[58] who passed the gas over active charcoal at 600° to 700° C. Hydrogen, methane and carbon were among the products formed, and the carbon, thus liberated, appeared to be an effective catalyst for the condensation reactions. About 70 per cent of the acetylene was converted into light and heavy oils in approximately equal proportions. The light oil contained 70 per cent aromatic hydrocarbons and 30 per cent unsaturated hydrocarbons. The addition of carbon dioxide to the acetylene increased the proportion of light oil and assisted in regenerating the catalyst.

Berl and Hofmann [59] obtained a yield of 98 per cent of liquid products by the pyrolysis of acetylene. An electrically heated copper block, which permitted the maintenance of a constant temperature, was used as a furnace. By placing this furnace in a vertical position the liquid reaction products could be easily withdrawn. Iron, silica, tin or calcium oxides were found to be unfavorable to the conversion. Good yields of aromatic hydrocarbons were, however, obtained with carbon as a contact agent at temperatures between 600° and 700° C.

The condensation of three molecules of acetylene to one molecule of benzene is an exothermic reaction. The heat thus liberated must be kept from the reacting gas and this, Berl and Hofmann reported, can be accomplished by mixing carbon dioxide with the acetylene. Carbon dioxide not only has a high specific heat but it is capable, as Fischer and his collaborators[60] have shown, of burning off carbon deposits in the furnace. Berl and Hofmann further observed that the addition of water vapor to the gases distinctly improved the polymerization of acetylene.

The importance assigned by earlier investigators to acetylene as an intermediate in the formation of aromatic hydrocarbons during pyrolytic reactions has been disproved by later work. It is almost certain that (with the possible exception of methane) the formation of aromatics by the pyrolysis of gaseous hydrocarbons takes place through the intermediate production of olefins and diolefins rather than of acetylene.

AROMATIC HYDROCARBONS FROM CYCLOPARAFFINS

Of the non-aromatic cyclic hydrocarbons, cyclohexane and its homologues appear to be most readily converted directly into benzene derivatives by heat in the presence of catalysts. Zelinsky and his co-workers[61] ascertained that the dehydrogenation of cyclohexane to benzene is a reversible reaction under certain conditions. In the presence of palladium or platinum black, benzene is readily hydrogenated to cyclohexane at 100° to 110° C., and at higher temperatures (the maximum being 300° C.) the dehydrogenation of cyclohexane to benzene predominates. Zelinsky also made the important discovery that palladium or platinum black are selective catalysts for the dehydrogenation of cyclohexane hydrocarbons but do not affect other cycloparaffin rings. For example, menthane and hexahydroxylenes can be dehydrogenated over platinum black at 300° to 310° C. to yield the corresponding aromatic hydrocarbons, cymene and the xylenes.[62] Certain cyclohexane homologues are, however, resistant to this dehydrogenation and Zelinsky[63] found that 1,1-dimethylcyclohexane was unchanged by passage over the platinum catalyst at 300° C.

The dehydrogenation of cyclohexane hydrocarbons to aromatics can be accomplished also in the presence of catalysts other than platinum or palladium, but side reactions involving the fission of C—C bonds occur at the same time. Sabatier and Senderens[64] reported that cyclohexane and some of its homologues are partly converted into aromatic hydrocarbons in the presence of nickel at about 280° C., methane and hydrogen being simultaneously formed. According to Zelinsky and Kommarewsky,[65] cyclohexane can be dehydrogenated to benzene and methylcyclohexane to toluene in the presence of nickel deposited on alumina at 300° to 310° C. without the formation of methane and other byproducts. Copper has also been suggested as a dehydrogenating catalyst for the conversion of cyclohexane hydrocarbons to benzene derivatives, but a much higher temperature (550° C.) appears to be required and carbon-to-carbon scission occurs with the simultaneous appearance of ethylene, propylene and butadiene.

The non-catalytic pyrolysis of cyclohexane and its homologues yields aromatic hydrocarbons but at the same time extensive carbon-to-carbon scission takes place forming methane, ethylene, ethane and butadiene.[66]

The dehydrogenation of naphthenes, or of petroleum fractions rich in them, is accomplished in the presence of certain catalysts containing cobalt or iron. An example of such a catalyst is one prepared by depositing a mixture of ammonium tungstate, cobalt nitrate and antimonic acid on active carbon and subjecting the mass to a stream of hydrogen sulphide at 350° C. for four hours.[67]

The cycloparaffins which do not contain rings of six carbon atoms apparently do not decompose directly into aromatic substances but isomerize first to straight-chain olefins. Secondary reactions at high temperatures (750° C.) undoubtedly convert the latter partly into aromatic hydrocarbons.

TECHNICAL PROCESSES

The most prominent feature in the technical development of the synthesis of aromatic hydrocarbons is the increasing attention directed toward the utilization of methane and its immediate homologues in natural gas as raw materials. Thus for example, Goudet[68] described a procedure for obtaining higher hydrocarbons from methane by heating this gas to 500° to 590° C., cooling suddenly to 250° to 350° C., and then submitting the gaseous product to the action of catalysts. The whole sequence of operations is conducted under high pressure.

In a process developed by the I. G. Farbenindustrie A.-G., methane, or gases containing methane, is passed over catalysts, such as the carbonates of the alkaline metals or the oxides or carbonates of magnesium or beryllium, at temperatures varying from 500° C. to 800° C. The reaction is carried out under pressure, which may be as high as 1000 atmospheres.[69] These same catalysts can be used, without the application of pressure, with the gases (containing both saturated and unsaturated, especially olefinic, hydrocarbons) from the low-temperature carbonization of carbonaceous materials.[70]

Another procedure for converting methane, or its gaseous homologues, into aromatic hydrocarbons consists of heating in two stages, first at temperatures of about 500° C., and subsequently as high as 950° C. Liquid hydrocarbons are separated after each stage. The reaction is carried out in tubes which may contain catalysts, such as silicon or graphite, with heating periods of 10 to 60 seconds.[71]

In addition to graphite and silicon, which may be used in the free or elemental state molded into bricks bonded with clay, alumina or water glass,[72] many other catalysts have been suggested. Examples are: firebricks or silicon bricks impregnated with copper salts, or refractory materials such as alloys of chromium and nickel, ferro-silicon, or silicon carbide[73]; oxides of chromium, tungsten, vanadium, or uranium, or mixtures of them[74]; chromium, tungsten, molybdenum, or alloys of these metals.[75] The last named are resistant to high temperatures and do not promote deposition of carbon. The elements selenium, tellurium and thallium, or their compounds, have also been proposed.[75a] The pyrolysis of gaseous paraffinic or olefinic hydrocarbons (at temperatures of 400° to 1100° C.) in the presence of the vapors of metals melting below 500° C. (the alkali metals excepted) has been described.[76] In general, catalysts for the conversion of gaseous paraffin hydrocarbons into aromatics may also be used for similar pyrolytic reactions with gaseous olefins. Aromatic hydrocarbons are made by passing methane, or other paraffin hydrocarbons, through heated non-metallic refractory chambers (Chamotte or silicon carbide) having the inside walls coated with a glaze of a silicate, phosphate, or borate of an alkali or alkaline-earth metal, or of copper, manganese, lead or chromium.[77] These catalysts are also said to prevent carbon formation.

Dunstan and Wheeler[78] reported the production of aromatics when a stream of gas, containing paraffins, is first gradually heated to a temperature (e.g., 550° C.) substantially below that required for decomposition, and then to a temperature (650° to 975° C.) at which the paraffins are decomposed and aromatics formed. Afterward the gas stream is expanded, cooled, and its velocity reduced, thus allowing deposition of the free carbon formed. The aromatic hydrocarbons are condensed and separated. If necessary the original gas is previously freed from hydrogen sulphide and condensible hydrocarbon vapors. The yield of aromatic hydrocarbons is said to be increased by dilution with an inert gas (steam) which is best introduced into the gas stream between the preheater and the reaction tubes. The reaction temperature is controlled at a point depending upon the paraffin or mixture of paraffins present. The suggested temperature ranges are 850°-975° C., 800°-900° C., 750°-800° C., 700°-800° C., and 650°-750° C., for methane, ethane, propane, butane; and pentane, respectively. For mixtures, a range of temperature is chosen suitable to the proportions of the constituents. The velocity of the gas in the preheater tubes and reaction tubes is so maintained that the flow is turbulent, giving good heat-transfer and maintaining the carbon particles in suspension. The residual gas, after the separation of free carbon and liquid aromatic hydrocarbons, may be utilized for the production of carbon black by combustion with a restricted supply of air, or it may be converted to oxygenated organic compounds such as alcohols, aldehydes or acids, particularly when it contains carbon monoxide or after the addition of that gas.[79]

Dunstan and Hague[79a] later employed a two-stage treatment for the production of aromatic compounds. In the first stage, the heating is conducted at 650°-800° C. under atmospheric pressure, which converts the paraffin hydrocarbons into olefins. In the second, the olefins are polymerized and condensed by heating at 350°-550° C. under pressures of 200 to 2000 pounds per square inch. To minimize the production of carbon, the apparatus is constructed of or lined with copper, aluminum or stainless steel.

In the process of Fischer and Pichler[80] methane, pure or diluted with other gases, is converted into benzene and other aromatic hydrocarbons by subjecting it to a temperature of 1000° to 1100° C. for a period of time not exceeding 1 second (best $\frac{1}{6}$ to $\frac{1}{20}$ second) in the absence of catalysts or oxygen-containing gases. Reaction is secured by passing the gas at a high velocity through narrow tubes maintained at the required temperature. Some free hydrogen, produced at the same time, may be reconverted to methane, e.g., by reaction with carbon monoxide in the presence of a catalyst, and the methane converted into additional aromatic hydrocarbons. Later Fischer[81] described an apparatus for this process consisting of a tower lined with silica and heated by furnace gases to the desired temperature. When sufficiently hot, a reverse (downward) current of methane is substituted, the products being removed from the base of the tower. As soon as the methane conversion falls off furnace gases are again led in, and the cycle is repeated as often as desired. A heat exchanger is arranged to preheat the methane and combustion gases alternately.

Lewis[82] described a procedure for the pyrolysis of natural gas in which about 90 per cent of the gas is conducted through tubes heated by the combustion of the other 10 per cent. The gases formed during the heat treatment are mixed with the hot products of combustion and the mixture is expanded, cooled, and passed through an absorber for the removal of benzene. The residual gases may be burned to yield carbon black and the waste heat utilized in preheating the raw gas.

According to Youker,[83] liquid hydrocarbons are obtained by heating natural gas at temperatures above 750° C. under pressures greater than 500 pounds per square inch.

Snelling[83a] heated gaseous hydrocarbons at 400° to 649° C. under a pressure of 800 to 3000 pounds per square inch and returned a portion of the uncondensed gas to the reaction zone for further treatment. The liquid products were separated by condensation under a lower pressure.

Either aromatic or olefinic hydrocarbons may be produced by the pyrolysis of mixtures of gaseous hydrocarbons (both saturated and unsaturated) at temperatures of 1000° to 1200° C. and at space velocities of 50 to 100 reciprocal minutes or more. For high yields of aromatic hydrocarbons lower space velocities are required and at higher space velocities olefins or diolefins are formed. The reactions may be carried out in two or more stages with the removal of light oils or olefinic hydrocarbons after each stage. Also each stage is effected at a higher temperature or a lower space velocity than the preceding one. The reaction chambers, which should be very narrow in relation to their other dimensions, may be made of carborundum, graphite or heat-resisting alloys. If the walls are coated with alumino-silicate refractories, such as sillimanite, an increased proportion of naphthalene is obtained. The intermediate products of pyrolysis include propylene, ethylene and acetylene, and the final ones are light oils, methane, hydrogen and carbon. For example, a gaseous mixture consisting of 45 per cent methane, 24 per cent ethane, 21 per cent propane, and 10 per cent butane gave 0.32 gallon of light oil per 1000 cubic feet in a one-stage treatment, and 1.08 gallons in a three-stage treatment.[84]

[83a] U. S. Patent 1,880,189, Oct. 27, 1932; assigned to Gasoline Products Co., Inc.; *Brit. Chem. Abs.* **B**, 1933, 852.

An apparatus for the conversion of methane into aromatic liquid hydrocarbons, described by Otto,[85] consists of a modified coke-oven setting, in which the gas is passed through channels in the brickwork or in which the ovens themselves are used as contact chambers. The necessary heat is provided by the combustion of gas in an adjoining chamber, with heat exchangers between the ingoing and outgoing gases to increase the economy of the system. A temperature range of 1040° to 1060° C. yields the best results with pure methane.

Wheeler and Fletcher[86] developed an apparatus for carrying out endothermic gas reactions, such as the pyrolysis of gaseous hydrocarbons to produce aromatic liquids, at temperatures above 1000° C. and at high space velocities. It consists of a series of unpacked reaction chambers which are long, deep, and very narrow and are placed between long, deep heating-flues. The width of these chambers is about one-half inch and they are made of refractory material. After the desired reactions have taken place the products are passed through heat exchangers for preheating the incoming gaseous reactants.

In the process of Wheeler and Francis[87] the pyrolysis of hydrocarbon gases to liquid hydrocarbons is combined with the production of carbon bisulphide without seriously affecting the yields of aromatic hydrocarbons normally obtained. The gaseous hydrocarbons are mixed with sulphur vapor and the mixture passed through a heated reaction zone at a high temperature and a high space velocity. Instead of sulphur vapor, substances which yield sulphur at high temperatures (e.g., hydrogen sulphide) may be substituted. The apparatus of Wheeler and Fletcher can be used for this purpose, and all of the sulphur is said to be converted into carbon bisulphide.

According to Bampfylde,[88] reaction chambers for the pyrolysis of hydrocarbons may be constructed of, or surfaced with, a special iron alloy containing 10 to 16 per cent of aluminum and as much as 6 per cent chromium. Such alloys are particularly useful in the treatment of gaseous paraffinic or olefinic hydrocarbons at 550° to 1250° C. to yield aromatic hydrocarbons, and in the formation of liquid polymers from gaseous olefins at 350° to 500° C. under elevated pressures.

The conversion of methane, or a gas rich in methane, into liquid hydrocarbons may be accomplished by bringing it into contact with catalysts consisting of, or coated with, chromium or graphite at 800° to 1200° C. The catalysts are heated either indirectly or by an electric current passed through them.[89]

Benzene and other aromatic hydrocarbons are obtained from ethane, propane, or butane, or mixtures of these hydrocarbons, by passing them downwards through a brick-packed tower at 800° to 950° C. The velocity of the gases through the tower is adjusted according to the temperature in the various sections.[90]

Several processes of the Ruhrchemie A.-G. relate to the conversion of aliphatic hydrocarbons, such as methane, into aromatic hydrocarbons in two stages. In the first stage acetylene is formed and in the second stage this hydrocarbon is polymerized to aromatics. In one procedure,[91] a partial transformation of the aliphatic hydrocarbons to acetylene is effected by heating to temperatures exceeding 1600° C. for a very short heating period (less than 0.001 second). The resulting gas mixture is then heated for a longer period at 450° to 1000° C. In this second stage catalysts may be employed. The gases are heated electrically, and the heat of the exit gas is used to preheat the incoming gases or to generate steam. In the second stage the temperature is maintained by the heat content of the gas from the first stage. In a modification,[92] the gas is heated in the first stage to temperatures above 1120° C., at reduced pressure, for somewhat longer periods (not more than 0.5 second). The resulting gas mixture is then subjected to a second thermal treatment by passage through an apparatus having hot walls (e.g., at 580° C.) opposite cold walls (75° C.), which may be water-filled tubes. Catalysts, such as a mixture of aluminum oxide and potassium oxide, can be used.[93]

Coxon[94] developed a method for the thermal treatment of gaseous paraffin or olefin hydrocarbons in which the gases to be pyrolyzed are preheated by mixing with another heated gas. The mixed gases are then passed into the reaction zone where they are kept, for a short time, at the temperature necessary for the conversion reactions.

Wheeler[95] suggested that the hydrogen, formed simultaneously with aromatic hydrocarbons during the pyrolysis of methane or ethane, be removed from the gaseous products of pyrolysis before these are subjected to further thermal treatment. This may be accomplished in several ways, as for example, by leading the gases over copper oxide heated to 250° C., by diffusion, or by converting the hydrogen into methane by catalytic reaction with the requisite quantity of carbon monoxide.

The conversion of olefins into aromatic hydrocarbons for use in antiknock motor fuel is of importance in the possible utilization of vapor phase cracking gas which contains large proportions of lower olefins.[96] Conversion is effected in two stages. In the first stage the olefins are led over a hot catalyst (such as charcoal at 400° C.) at high pressures (e.g., 40 atmospheres). The liquid hydrocarbons are dehydrogenated in a second stage by passage over a catalyst of ammonium molybdate at 600° C. under 5 atmospheres pressure.

Other catalysts suggested for converting olefins into liquid hydrocarbons of low boiling point are, (1) gold, silver or copper in the form of turnings or gauze or as the lining of the reaction tube; (2) compounds of the alkali metals, particularly oxygen-containing compounds, to which may be added other metallic salts or oxides; and (3) salts of the acids of phosphorus, boron or antimony, their reduction products, or the acids or anhydrides themselves in the solid form supported on a carrier. Materials such as iron or nickel which promote the formation of carbon are excluded, as are also rough surfaces. For this reason the interior of the reaction vessel may be lined with copper, silver quartz or ferrosilicon or may be constructed of materials comprising free silica.[90a]

The gases should be free from sulphur. Methane, or gases containing or yielding methane, may be added and the residual gases after pyrolysis may be recirculated. At temperatures of 300° to 400° C. the products consist principally of liquid olefins and at 500° C. benzene and naphthenes predominate. The latter are converted to aromatics by catalytic dehydrogenation at temperatures above 500° C.[97] If desired, the olefins may be isolated first from the olefin-containing gas (by fractional liquefaction or absorption) and then converted into liquid hydrocarbons.[98]

Certain alloys have been proposed also as catalysts, among which may be mentioned brass, bronze, manganese-copper, or tinned, galvanized or chromium-plated iron and copper.[99]

Ramage[100] suggested passing water gas mixed with gaseous olefins, of not more than five carbon atoms per molecule, at atmospheric pressure through a series of tubes containing finely divided iron maintained at 537° to 965° C. (1000° to 1500° F.). The issuing gases contain large proportions of aromatic hydrocarbons which can be condensed or scrubbed out.

The conversion of mixtures of olefins and acetylene into higher hydrocarbons can be effected at high temperatures under any pressure without carbon deposition if the heated gases come into contact only with elements of Group IV (tin, silicon, lead, or carbon as graphite), or with zinc or aluminum or alloys of the latter metals. Thus, an oil is obtained when a mixture of ethylene and acetylene is led through an aluminum tube containing silicon and heated externally to a temperature of 525° to 600° C. At lower temperatures using a manganese-copper tube lined with tin, this gaseous mixture yielded a condensate containing about 13 per cent butadiene. Benzene hydrocarbons are obtained when tubes of manganese-copper or brass, lined with zinc, are employed.[101]

According to Wheeler and McAulay,[102] olefinic gases are converted into aromatic hydrocarbons by passage through tubes heated to temperatures above 1000° C. at space velocities exceeding 50 reciprocal minutes. For example, ethylene conducted at a space velocity of 6400 reciprocal minutes through a reaction zone maintained at 1100° C. gave about 30 per cent of light (aromatic) oil. The exit gases contained about 8 per cent acetylene.

For the production of higher-boiling olefinic or aromatic hydrocarbons,[103] gaseous olefins are heated under pressures as high as 1000 atmospheres at 350° to 800° C. in the presence of small pieces or bricks of elemental silicon or a ferro-silicon alloy containing a large proportion of silicon. The apparatus is made of materials resistant to the action of hydrogen sulphide and which do not catalyze the deposition of carbon. Such materials are "V2A" steel or steel containing molybdenum and tungsten or alloys of chromium and nickel. The operating conditions may be varied to produce a preponderance of either higher olefins or aromatic hydrocarbons. Egloff[103a] heats the gas which separates from the distillate resulting from the cracking of oils to about 650° to 1000° C. under superatmospheric pressure. The pressure is then lowered and the gases submitted to the action of ultraviolet light.

Ethylene or its homologues are also polymerized by heating in the presence of an inert liquid such as mineral oils, vegetable oils, phenols, water or "Edeleanu extract".[103b] A high temperature and pressure are maintained. For example, ethylene is heated with paraffin oil to 420° C. under a pressure of 45 atmospheres.

Propylene, or gases containing 20 per cent or more of propylene, may be converted to aromatic hydrocarbons or acetylene by pyrolysis at 700° to 900° C. in an apparatus constructed of nickel-chromium steel or of silica.[104] Hercourt[104a] suggested a method for the removal of organic or mineral impurities from crude benzene and other hydrocarbons by bringing the liquids into contact with aluminum in the presence of steam. The aluminum is previously activated by traces of mercury or salts of mercury.

Rembert[104b] mixed crude oil in finely divided form with non-oxidizing gases preheated to above 1350° C., attaining almost instantaneously an equilibrium temperature above 500° C. The mixture was then passed through an elongated reaction zone, at the end of which the gases were led into a liquid such as oil or water to cool them instantly to stop reaction.

MANUFACTURE OF DIPHENYL

The pyrolysis of aliphatic hydrocarbons eliminates hydrogen from the molecule and forms various types of unsaturated hydrocarbons, followed (on continued pyrolysis) by cyclicization of the unsaturated hydrocarbons to yield aromatics and finally condensed or polycyclic compounds. In the preceding discussion, the reactions leading to the formation of aromatic hydrocarbons have been considered in some detail. Such reactions include not only dehydrogenation and cyclicization but also in many instances a splitting of the molecule with the simultaneous formation of hydrocarbons of low molecular weight (e.g., methane, ethane and ethylene). Aromatic hydrocarbons, unless they have aliphatic side-chains, do not exhibit such reactions, but undergo condensation accompanied by the elimination of hydrogen.

In 1866 Berthelot[105] observed that benzene vapors when passed through a red-hot tube are converted to a considerable extent into diphenyl, according to the reaction:[106]

$$2C_6H_6 \longrightarrow C_6H_5C_6H_5 + H_2$$

The production of this hydrocarbon, however, has been put on a commercial basis only during the past decade. In the petroleum industry diphenyl has been employed as a material for high temperature vapor phase heat transfer.[107] A eutectic mixture of 26 per cent diphenyl and 74 per cent of diphenyl oxide[108] as well as mixtures of diphenyl and naphthalene[109] have been suggested for the same purpose.

[106] This reaction was investigated also by Schmidt and Schultz. *Ber.*, 1872, **5**, 682; *Ann.*, 1880, **203**, 118; Olgiati, *Ber.*, 1894, **27**, 3387; McKee, *J.S.C.I.*, 1904, **23**, 403; Smith and Lewcock, *J.C.S.*, 1912, **101**, 1453; Rittman, Byron and Egloff, *Ind. Eng. Chem.*, 1915, **7**, 1019; Zanetti and Egloff, *Ind. Eng. Chem.*, 1917, **9**, 350. The equilibrium constants of this reaction at temperatures of 845°, 900°, and 920° C. have been determined by Vvedenskii and Frost, *J. Gen. Chem.* (*Russia*), 1932, **2**, 542; *Chem. Abs.*, 1933, **27**, 888.

The manufacture of diphenyl has been described by Scott.[110] Benzene vapor is passed through a metal coil immersed in a lead bath maintained at 600° to 650° C. As the vapors leave the coil they bubble up through the molten lead into a similar coil which is immersed in a second lead bath kept at 750° to 800° C. The diphenyl so produced is conducted at a high velocity into a water-cooled condenser. In another process the benzene vapors are led through a reaction chamber at 800° C. containing contact agents which minimize the deposition of carbon.[111] Such substances are the sulphides of cobalt, iron, copper, molybdenum, arsenic, tin or zinc; the chlorides of nickel or antimony, potassium chromium sulphate, or the metals selenium, arsenic, silicon, antimony, or molybdenum. Other catalysts which have been suggested for the dehydrogenation include difficultly fusible oxides, vanadates, chromates, tungstates, molybdates, aluminates, and zincates, such as those of calcium, magnesium, titanium, cerium, zirconium, thorium and beryllium.[111a]

Govers[112] used a bath of molten cryolite or other non-metallic liquid at 750° C., and heated the benzene vapor to 650° C. prior to its passage through these liquids. A conversion of eight per cent was obtained. In another process[113] the vapors of benzene are brought into contact with a catalyst, consisting of 80 parts of potassium carbonate, 50 parts of thorium oxide and 5 parts of cobalt oxide, maintained at a temperature of 760° C.

An apparatus for this reaction has been described also by Hixon and his collaborators.[114] Their results indicated that the optimum temperature for the conversion is about 740° C. The yields of diphenyl in all instances were increased by using pressures greater than atmospheric. At a temperature of 740° C., a pressure of 8 atmospheres, and a rate of flow of about 400 cc. of benzene vapor per 164 cc. of available reaction space per hour, about 20 per cent of the benzene is pyrolyzed to diphenyl. Under the same conditions the chemical efficiency of the process may reach 98 per cent, i.e., only a negligible formation of by-products occurs. Increasing the rate of flow decreases the proportion of diphenyl formed. Complex diaryl compounds having boiling points higher than diphenyl are obtained by vaporizing pure commercial benzene or commercial 90 per cent benzene.[114a] The benzene is first heated to a temperature just below that at which diaryl compounds are formed, and is then rapidly raised to a point at which complex diaryl compounds result.

Chapter 6

Action of Aluminum Chloride on Hydrocarbons

Many examples of the pronounced influence exerted by various catalysts on the thermal reactions of hydrocarbons have been noted in the preceding pages. Anhydrous aluminum chloride, however, is unique in this respect and therefore it is desirable to discuss its effect on the thermal decomposition of each series of hydrocarbons separately. Aluminum chloride induces molecular disintegration of higher hydrocarbons at relatively low temperatures, the products being low-boiling saturated hydrocarbon oils. It is also an active agent for polymerizing unsaturated hydrocarbons, though at higher temperatures the decomposition reaction (producing low-boiling paraffin hydrocarbons) occurs simultaneously with that of polymerization. Whatever may be the mechanism of catalysis by other active bodies, the action of aluminum chloride is a purely chemical process through reactions forming double compounds with certain hydrocarbons, probably unsaturated ones.

Friedel and Crafts, whose names are associated with certain classic reactions catalyzed by aluminum chloride, were the first to notice that it might be employed in the production of light oils from heavier ones by cracking.[1] In 1881 Gustavson [2] found on treating hydrocarbons obtained by fractionating American gasoline or Caucasian kerosene with anhydrous aluminum bromide and hydrobromic acid that two layers were formed. The lower layer had the approximate composition $AlBr_3 \cdot C_4H_8$ and decomposed at 120° C. to yield gaseous hydrocarbons.

Since that time, processes for the production of gasoline from heavy petroleum fractions using aluminum chloride have been developed by the Continental Caoutchouc and Gutta Percha Co.,[3] Gray,[4] Cobb,[5] Koetschau,[6] Heusler,[7] Alexander and Taber [8] and by McAfee, whose processes, mentioned below, have been used in a commercial way.

PRODUCTION OF GASOLINE WITH ALUMINUM CHLORIDE

The two most important processes advocated for the production of gasoline from heavier oils by treatment with aluminum chloride are those of Gray and of McAfee. The latter process has been exploited by the Gulf Refining Co. and the former by The Texas Company. Gray stated in the description of his process that the low-boiling products of the reaction possess end-points approximately the same as the temperature at which the decomposition is effected, and in operating at a temperature of 550° to 600° F. (288° to 316° C.) a dephlegmator should be used to return the higher-boiling fractions to the still.

McAfee emphasized not only the conversion of high-boiling hydrocarbons to lower-boiling ones but also the improvement in the quality of the residue in the reaction vessel. For a description of the McAfee process and an account of its numerous details the original references should be consulted.[9] The operation is conducted by adding 5 to 8 per cent of anhydrous aluminum chloride to the oil, previously dried at 300° to 350° F. (150° to 175° C.) for some time, and heating the mixture to 550° F. (290° C.) or higher in a still fitted with a stirring device. A differential condenser returns all the products of the reaction except those of desired volatility. It is possible to obtain from 15 per cent to as high as 60 per cent yields of gasoline, consisting principally of saturated hydrocarbons, from a single distillation whose period is limited by various factors to 24 to 48 hours. Because aluminum chloride sublimes at 181°-185° C., sustained high temperatures cause a loss of catalyst, which can be avoided by pressure operation.

Some details of the reactions taking place during such a process have been supplied by Dubrov, Lavrovsky, Goldstein, Fish and Mikhnovskaya.[10] In addition to the splitting of the larger molecules into smaller ones, polymerization, rearrangement and carbonization take place simultaneously; and because of the content of hydrogen in the original hydrocarbons, the maximum yield of light products which can be expected is limited to 70 per cent. The gasolines so produced contain large percentages of saturated hydrocarbons of the naphthene and aromatic types; in one instance analysis indicated that the gasoline contained about 5 per cent aromatics, 41 per cent naphthenes, and 38 per cent paraffins. The residual oils after the distillation of the gasoline and kerosene fractions are said to be high grade lubricants of a saturated character.

The rate of decomposition of the oil by aluminum chloride is materially decreased by the presence of potassium and, particularly, sodium compounds. On the other hand, as much as 1 per cent of ferric chloride, silicon tetrachloride or aluminum oxide does not affect the yield. About 10 per cent of aluminum chloride is used in the preparation of gasoline, but about 5 per cent is sufficient when lubricating oils of high viscosity-index and low pour points are desired. It was noted also that paraffin wax which had been treated with aluminum chloride readily yielded solid acids on oxidation. Waterman and van Soest[11] obtained small yields of gasoline (18 to 23 per cent) on cracking Rangoon paraffin wax with aluminum chloride.

After treatment with aluminum chloride and removal of the products, the residue in the still consists of granular coke of little value containing aluminum chloride,[12] and heavy oils which can be worked up into lubricating and similar oils.

Graetz[13] treated dehydrated and refined Gabian petroleum (initial boiling point 217° C.) with increasing amounts of aluminum chloride; he obtained a maximum yield (about 75 per cent) of products distilling up to 210° C. with 9 per cent of aluminum chloride. With crude petroleum, the same maximum amount of light products was found but 14 to 15 per cent of aluminum chloride had to be used. This was due to the effect of water, sulphur and oxygenated compounds in the crude. He maintains that the mechanism of the cracking is first, the formation of a hydrocarbon-metal chloride complex and second, breaking of the complex at the distillation or decomposition temperature of the metal chloride accompanied by the severing of the carbon chain. The minimum cracking temperature of oil is 160° C.; at 200° C. the reaction is fairly fast. The aluminum chloride complex is stable up to 180°-190° C., it is fairly active at 190°-210° C. and completely decomposed at 230°-240° C. It would therefore be better, according to Graetz, to carry out the cracking at 240° to 245° C. He also found that sulphur, stannic, mercuric, cupric, ferric and sodium chlorides form complexes with oil on heating for some time, but in order that cracking may be catalyzed by a metal chloride the latter must be volatilizable or decomposable between 190° and 210° C. The complexes formed by chlorides boiling at a lower temperature (sulphur chloride and stannic chloride) decompose below the minimum cracking temperature; the high-boiling chlorides such as ferric chloride are very stable so that cracking cannot take place below 250°-260° C.

The economic success of any of these processes depends largely upon the cost of the aluminum chloride.[14] Methods have been developed for producing this material at a cost low enough to permit of its extensive use in the industries.[15] Aluminum chloride was first prepared by Oerstedt[16] by passing dry chlorine gas over alumina mixed with powdered charcoal and ignited in a porcelain tube. It was from this compound that Wöhler[17] succeeded in isolating the element. He also observed that on heating aluminum to redness in a current of chlorine, aluminum chloride was formed and sublimed, a method still used for the preparation of the purest samples.

A general procedure for obtaining anhydrous chlorides by heating the oxide of the metal with phosgene was proposed by Chauvenet.[18] The treatment of oxide ores with carbon monoxide or carbon, and chlorine or with phosgene was described by Brode and Wursten,[19] Alexander,[20] McAfee,[21] and McAfee and Roberts.[22]

McAfee[23] described the large-scale production of this material by the Gulf

Refining Co. Crude bauxite ore is calcined in an internally heated rotary kiln at about 1800° F. (980° C.) to drive off moisture. It is then mixed with coking coal in the proportion of 1 part of coal to 3 parts of bauxite by weight; the mixture is pulverized, mixed with a liquid binder and briquetted; and the briquettes are preheated to about 1500° F. (815° C.) to expel volatile matter, forming a hard composition of 82 per cent bauxite and 18 per cent carbon. The hot briquettes are charged into a vertical chlorinating furnace, and the temperature is raised to 1600° F. (870° C.) by a short air-blow, after which chlorine is passed downwards through the charge for 8 to 10 hours. Aluminum chloride passes from the bottom to a firebrick cooler and is deposited as a powder, 75 per cent passing a 10-mesh screen.[4]

The disadvantages of treatment with aluminum chloride as a refining process are the cost of the reagent, the production of corrosive hydrogen chloride fumes during the process, and the difficulties of disposing of the coke residues. The gasolines produced by this process, however, contain mainly saturated hydrocarbons and are therefore more stable toward oxidation than those from the usual cracking operation. The use of other anhydrous chlorides such as ferric chloride, antimony chloride, stannic chloride, titanium chloride, and zinc chloride has been investigated[24] but none of these is known to be used at present.

Lidov[25] found that in the production of low boiling hydrocarbons from high boiling ones it is advantageous to form the anhydrous catalyst during the process. For example, solar oil is mixed with iron or with aluminum, heated for 2 to 3 hours at 250° to 280° C., and during this time a current of dry hydrogen chloride gas is passed into the mixture. In this manner a yield of 65 per cent of benzine, of specific gravity 0.865, is obtained with iron and 75 per cent with aluminum. The highest yield of aromatic compounds is obtained by operating at 600° C. and under a pressure of 18 atmospheres. Bespolov and Degtyareva[25a] investigated the possibilities of refining cracked gasoline with aluminum chloride. They found at least 1 per cent by weight of aluminum chloride necessary to produce a marketable gasoline. The sulphur content was reduced by about 50 per cent, but gum formation and odor increased in storage.

ACTION OF ANHYDROUS ALUMINUM CHLORIDE ON PARAFFIN HYDROCARBONS

Pictet and Lerczynska[26] treated various higher fractions of American and Russian petroleum with 10 per cent of aluminum chloride and obtained benzine fractions corresponding to almost pure paraffin hydrocarbons. When the residuum had been freed from aluminum chloride by washing with water, there remained a black pitch, resembling asphalt, partly soluble in alcohol and ether and completely soluble in chloroform. Analysis of this pitch showed it to consist of 92.2 per cent carbon and 7.2 to 7.6 per cent hydrogen, corresponding to the empirical formula C_nH_n. Pictet and Lerczynska were of the opinion that aluminum chloride caused the splitting off of side chains from naphthene hydrocarbons and polymerization of the unsaturated residue. Zelinsky[27] obtained similar results with heavy petroleum oils and also found that the lower fraction (boiling up to 70° C.) of the gasoline obtained by the aluminum chloride process consisted largely of paraffin hydrocarbons. The lower petroleum fractions boiling up to 125° C. were found to be much more resistant to the action of the chloride than the higher ones. Naphthenes were entirely absent from the products of the action of aluminum chloride on paraffin wax, only paraffin hydrocarbons being present.

Comprehensive study of the behavior of aluminum chloride with hydrocarbons was conducted by Grignard and Stratford[28] who determined the action of 20 to 30 per cent of this reagent on various pure hydrocarbons at temperatures ranging from 120° to 150° C. All the paraffin hydrocarbons studied, namely octane, diisobutyl, decane, diisoamyl, and heptadecane, split off n-butane. When the molecule contained ten or more carbon atoms butane was split off simultaneously from both ends. The unsaturated residues polymerized with the production of complex hydrocarbons.

Cox[29] found that when nonane was heated for 8 hours at 110° to 120° C. with aluminum chloride, butane was produced, and concluded that the residual pentene was partly converted into cyclopentane, this view being supported by the fact that cyclopentane is not affected by heating with aluminum chloride.

Further work on the action of aluminum chloride on the paraffin hydrocarbons was reported by Jurkiewicz and Kling.[30] Decomposition was effected in sealed glass tubes over the temperature range 250° to 500° C. Methane was not converted into higher hydrocarbons but hydrogen was evolved and carbon deposition was noticed at 500° C. Ethane began to decompose at 320° C. and at 410° C. the formation of oily substances and carbon had begun, becoming appreciable at 500° C. These oily substances, which were considered to be addition compounds of aluminum chloride and hydrocarbons, were encountered also with other hydrocarbons studied. Synthesis of higher hydrocarbons from isobutane was noted at 245° C. The temperature range 370° to 390° C. was considered to be a critical one, above which the reaction of aluminum chloride is no longer specific. The observation was made that the resistance of paraffin hydrocarbons to the action of aluminum chloride decreases with increasing molecular weight.

Schneider[31] studied the action of aluminum chloride on hexane and isohexane and found that a synthesis of more complex molecules occurs, as well as decomposition to smaller ones. The gaseous decomposition products consisted of butane, a little propane, pentane and unchanged hexane, but no methane. The liquid residues consisted of hydrocarbons boiling higher than the original material. Unsaturated hydrocarbons were retained in the aluminum chloride sludge and were recovered by decomposing it with ice water.

Butane was reported[32] as the principal constituent of the gas produced by the action of aluminum chloride on various Russian petroleum oils.

Summing up, therefore, we may conclude that the lower paraffin hydrocarbons are relatively resistant to the action of aluminum chloride, the synthesis to higher hydrocarbons taking place at elevated temperatures accompanied by some decomposition. The higher hydrocarbons, on the other hand, react at much lower temperatures and tend to split off lower hydrocarbons (chiefly butanes) followed by polymerization of the unsaturated residues.

ACTION OF ANHYDROUS ALUMINUM CHLORIDE ON OLEFINS

The chief action of aluminum chloride on olefins is one of polymerization but this reaction may be obscured by extensive decomposition resulting in the formation of lower paraffins and higher-boiling hydrocarbons of lower percentage hydrogen than the original hydrocarbon.[33] At ordinary temperature and pressure anhydrous aluminum chloride slowly adsorbs ethylene but most of the olefin is recovered on heating, only a small amount of residual red oil being obtained.[34] Isobutene and aluminum chloride yield colorless oils, and also dark red oils which contain 11.5 per cent aluminum and further react with isobutene. Leenderste, Tulleners and Waterman[35] observed that the chloride has very little effect on isopropylethylene at —80° C. A slight rise in the temperature, however, brought about the formation of viscous and sticky polymerized bodies.

[32] Dubrov, Lavrovsky, Goldstein, Fish and Mikhnovskaya, *loc. cit.*

Szayna[36] investigated the reaction between the lower olefins and aluminum chloride. He noted that ethylene reacted with difficulty at 100° C. and 150° C., yielding only small quantities of condensed products. Under similar conditions other olefins gave a gas, liquid hydrocarbons, and an organo-metallic compound. The gas was composed exclusively of butane. The lower-boiling liquids were chiefly paraffins and the heavier fractions consisted of cycloparaffins together with small amounts of unsaturated hydrocarbons. The organo-metallic compound was a dark brown viscous oil, decomposable by water, and had the empirical formula $AlCl_3(C_4H_x)_n$. The oil from this complex, after hydrolysis, corresponded with either $(C_8H_{12})_n$ or $(C_8H_{18})_n$, and its properties indicated the presence of cyclic unsaturated hydrocarbons.

Ipatiev and Rutala[37] studied the influence of catalysts, such as aluminum and zinc chlorides, on the condensation of ethylene under pressure. In the presence of zinc chloride at 70 atmospheres pressure polymerization took place at 275° C., the liquid products consisting of pentane, isopentane, hexane and higher paraffins, together with olefins of 6 to 9 carbon atoms.[38] Under 70 atmospheres pressure at ordinary temperature freshly prepared aluminum chloride induced polymerization to a greenish-red liquid containing paraffins in the lower fractions. At 200° C., only a carbonaceous residue was obtained. Prior to the work of Ipatiev and Rutala on ethylene, the polymerizing effect of aluminum chloride on other unsaturated hydrocarbons had been demonstrated by Heusler,[39] and the polymerization of amylene in the presence of that reagent had been studied by Aschan[40] and by Engler and Rutala.[41] The latter investigators found that the lower-boiling products consisted chiefly of paraffins, the cycloparaffins predominating in the fractions boiling above 175° C. Furthermore, they obtained an oil containing 87 per cent carbon, having a composition corresponding to C_nH_{2n-6} and possessing the properties of naturally occurring lubricating oil.[42] Steinkopf and Freund[43] observed that the reaction of aluminum chloride on turpentine oil yields products of a nature similar to those obtained from straight-chain olefins.

Stanley[44] examined the reaction between aluminum chloride and ethylene under pressures up to 50 atmospheres at ordinary and elevated temperatures in the presence of a diluent such as aromatic-free petroleum ether. At ordinary temperatures the reaction was rather slow, and yielded a free oil (an oil not combined with aluminum chloride) and a viscous, pasty organo-metallic compound from which some oil which had combined was obtained on decomposition with water. The free oil consisted mostly of liquid saturated hydrocarbons containing from 10 to 45 carbon atoms per molecule. The lower-boiling fractions were paraffins but the main part of the oil consisted of saturated hydrocarbons of the formula C_nH_{2n}, presumably cycloparaffins. The oil liberated from the organo-metallic compound consisted of a complex mixture of hydrocarbons with from 10 to more than 50 carbon atoms per molecule, apparently unsaturated and containing less hydrogen than required by the formula C_nH_{2n}. The oil was regarded as being composed of unsaturated hydrocarbons of the olefin series mixed with hydrocarbons of lower hydrogen content (probably unsaturated cyclic hydrocarbons). Stanley found that the condensation of ethylene under pressure was much more rapid at higher temperatures but the life of the catalyst was shortened under these conditions and gaseous paraffin hydrocarbons appeared. As before, free oil and aluminum chloride double compounds were formed but these differed considerably from the products obtained at lower temperatures. The organo-metallic complex tended to contain greater proportions of combined carbon with rising temperature. The free oil formed at higher temperatures was clear and contained large proportions of low-boiling constituents. The low-boiling fractions consisted of paraffin hydrocarbons of five or more carbon atoms. The higher-boiling fractions contained compounds deficient in hydrogen corresponding to the formulas C_nH_{2n-6}, C_nH_{2n-8}, and C_nH_{2n-10}, probably polynuclear naphthenes. The primary reaction was considered to be polymerization to higher olefins which combined with the aluminum chloride to form organo-metallic complexes. Isomerization of some of the higher olefins to the corresponding cycloparaffins sufficed to explain the formation of the saturated free oil at lower temperature. At higher temperatures the processes of polymerization and isomerization were attended by extensive decomposition, resulting in the splitting off of lower paraffins with subsequent polymerization of the unsaturated residues. These three reactions, namely, polymerization to higher olefins, isomerization of these olefins to the corresponding cycloparaffins, and the splitting off of lower paraffin molecules from the more complex hydrocarbon molecules, are undoubtedly the principal changes which occur through the action of aluminum chloride on olefin hydrocarbons.

Henderson and Gangloff[45] isolated numerous compounds of olefins and aluminum chloride formed by passing the unsaturated hydrocarbon into a solution of aluminum chloride in methyl or ethyl alcohol. Thus, in methyl alcohol ethylene formed a substance of the approximate formula $AlCl_3 \cdot C_2H_4 \cdot CH_3OH \cdot H_2O$, and amylene gave $AlCl_3 \cdot C_5H_{10} \cdot CH_3OH$. There appears to be little doubt, according to these investigators, that in the catalytic oil-cracking processes, the catalyst combines with certain products of the reaction, thus preventing the distillation of the unsaturated portion of the oil.

The polymerizing action of aluminum chloride on olefins requires special consideration on account not only of the theoretical interest associated with the reaction but also of the great technical importance which processes of this character are assuming, particularly in the production of synthetic lubricants. The action of aluminum chloride on hydrocarbons is undoubtedly a special case of the Friedel-Crafts reaction, which is also catalyzed by other anhydrous chlorides.

---

[45] *J.A.C.S.*, 1916, **38**, 1382; 1917, **39**, 1420.

Thus, Pictet and Lerczynska[46] found that anhydrous ferrous or ferric chlorides could be similarly used in the cracking of hydrocarbons; but their action is weaker and requires higher temperatures than aluminum chloride.[47]

The polymerization of gaseous olefins by aluminum chloride to yield viscous oils capable of use as lubricants is receiving attention, especially in countries where supplies of crude petroleum are not available. The question of the production of synthetic lubricants is discussed in a separate section later.

Although this discussion has been restricted largely to the action of aluminum chloride on olefins, it should be noted that the polymerizing action of zinc chloride has been investigated by Kondakov[48] and that of boron trifluoride by Butlerov and Gorianov[49] and by Otto and his associates.[50] According to Otto,[51] oils which very closely resemble lubricating oils in their flash points and viscosities result from the polymerization of ethylene in the presence of boron fluoride. These polymerizations, however, are discussed with greater detail in Chapter 26.

ACTION OF ANHYDROUS ALUMINUM CHLORIDE ON CYCLOPARAFFINS

According to Gurwitsch and Moore,[52] naphthenes combine with aluminum chloride to form orange-colored viscous liquids, which are decomposed by water to yield condensation products, cyclopentane derivatives being decomposed more quickly than cyclohexane derivatives. On the other hand, Cox[53] found that cyclopentane is not affected by heating to 110° to 120° C. with aluminum chloride and Koetschau[54] observed that cyclohexane and methylcyclopentane are produced by heating hexane at 120° C. under pressure with the chloride.

Transformation of cyclohexane to methylcyclopentane derivatives, as well as dehydrogenation of cyclopentane derivatives, has been noted in other instances. Unger[55] reported that acetyl chloride reacts with cyclohexane in the presence of aluminum chloride to yield derivatives of methylcyclopentane and methylcyclopentene. According to Nenitzescu and Cantuniari,[56] methylcyclopentane, under the same conditions, forms 2-acetyl-1-methylcyclopentane and 2-acetyl-1-methylcyclopentene. The formation of the unsaturated ketone was shown to result from the presence of water in the aluminum chloride. During the reaction between cyclohexane and acetyl chloride, some acetaldehyde is produced. The hydrogen required for the reduction of acid chloride to the aldehyde is apparently derived from the saturated ketone formed by the reaction of cyclohexane and acetyl chloride. Another instance of a similar reduction is that occurring when 2-acetyl-1-methylcyclopentane dissolved in cyclohexane is treated with benzoyl chloride and aluminum chloride. No reaction was detected between the cyclopentane derivative and benzoyl chloride which was reduced to benzaldehyde with the simultaneous formation of an equivalent quantity of the hydrocarbon $C_{12}H_{22}$ from the cyclohexane.

Nenitzescu and Cantuniari[57] observed that when cyclohexane is boiled for several hours with anhydrous aluminum chloride, it is practically unchanged, but under the influence of aluminum chloride containing water it is converted largely into methylcyclopentane. The maximum yield is about 20 per cent. The same equilibrium can be reached by starting with methylcyclopentane. No evidence of the formation of dimethylbutane was obtained.

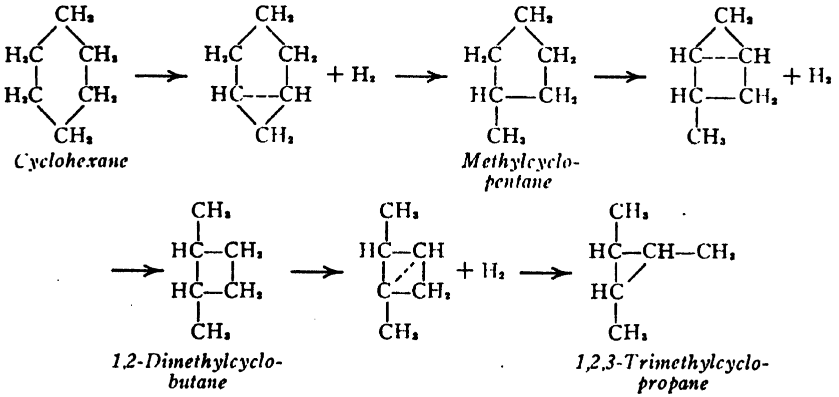
Zelinsky and Tarassova[58] pointed out that the isomerization of cyclohexane to methylcyclopentane does not take place quantitatively during the Friedel-Crafts reaction, but rather that its extent depends upon the experimental conditions. Furthermore, the production of unsaturated ketones by the reaction between acetyl chloride and cyclohexane is diminished by using an excess of aluminum chloride. In other words, an excess of aluminum chloride restricts the dehydrogenation of cyclohexane. The use of a poisoned catalyst (for example, technical aluminum chloride containing 3 per cent ferric chloride) increases the proportion of unsaturated ketones formed. The hydrogen liberated during the dehydrogenation reaction reduces the acid chloride to the aldehyde.

An unusual molecular rearrangement was observed by Hopff.[59] When cyclohexane is treated with carbon monoxide in the presence of aluminum chloride hexahydrobenzaldehyde is not formed but 1-methyl-2-cyclohexanone. Here no contraction of the ring takes place but rather a migration of a group from the nucleus to form a side chain.

Treatment of cyclohexane with aluminum chloride or bromide followed by dehydrogenation over a platinized carbon catalyst yielded methylcyclopentane, benzene, and dimethylcyclobutane. Aluminum bromide was found to dehydrogenate the latter compound to 1,2-dimethyldicyclo-[0,1,1]-butane, to which hydrogen adds yielding 1,2,3-trimethylcyclopropane.[60] These various steps, beginning with cyclohexane, may be illustrated as follows:



Zelinsky and Smirnov[61] noted that the decomposition of heptanaphthene (isolated from petroleum) by aluminum chloride in the presence of hydrochloric acid resulted in the formation of isobutane and an aluminum chloride-hydrocarbon complex $AlCl_3 \cdot C_4H_8$.

From their work on the decomposition of Galician, Austrian, American and Caucasian heavy oils by anhydrous aluminum chloride, Pictet and Lerczynska[62] concluded that side chains split off from naphthenic hydrocarbons with formation of a paraffin and the unsaturated cyclic residue polymerizes. This conclusion was substantiated by the comprehensive work of Grignard and Stratford.[63] These latter workers found that, by heating at 120° to 150° C. in the presence of 20 to 30 per cent of aluminum chloride, cyclohexane and methylcyclohexane are not changed, but both 1,2- and 1,4-dimethylcyclohexanes are isomerized to the 1,3-compound, the 1,4-compound isomerizing more readily. Derivatives of cyclohexane with side chains of 2 or 3 carbon atoms are converted by isomerization chiefly into the 3-methyl derivatives. For example, 1,3-diethylcyclohexane yielded largely tetramethylcyclohexane and only small quantities of butane. The three isomeric butylcyclohexanes form paraffins to the extent of 13 to 15 per cent, the products being n-butane from the normal and secondary isomers and a mixture of n- and isobutanes from tertiary butylcyclohexane. The principal reaction is an isomerization to a mixture of tetramethylcyclohexanes. Amyl- and isoamylcyclohexanes are decomposed to the extent of 70 per cent and 42 per cent, respectively, both yielding butane. Isomerization also occurs to form a mixture of tetramethyl- and pentamethylcyclohexanes.

It appears, therefore, that cyclohexane, cyclopentane and their immediate homologues are fairly stable toward anhydrous aluminum chloride. Cyclohexane and its derivatives, however, oftentimes undergo molecular rearrangement or dehydrogenation. Derivatives of the naphthene hydrocarbons, particularly those with long side chains, tend to split off the side chains with the formation of lower paraffin hydrocarbons (and subsequent polymerization of the unsaturated cyclic residue), or to isomerize to other polymethylene derivatives.

ACTION OF ALUMINUM CHLORIDE ON AROMATIC HYDROCARBONS

The most important reaction of aluminum chloride with aromatic hydrocarbons yields polynuclear hydrocarbons by dehydrogenation. This dehydrogenating action is facilitated by substances capable of taking up hydrogen.[64] Friedel and Crafts[65] found that at 180° C. in the presence of aluminum chloride benzene yields diphenyl, toluene and ethylbenzene, together with some ditolyl. As shown by Homer,[66] these changes take place even more readily with naphthalene, which yields dinaphthyl and higher hydrocarbons.

The condensation of higher aromatic hydrocarbons to produce others containing a larger number of aromatic nuclei also takes place under the influence of aluminum chloride. Scholl and his collaborators,[67] who paid particular attention to the use of aluminum chloride in the production of polynuclear aromatic substances, found that dinaphthyl could be readily converted into perylene,

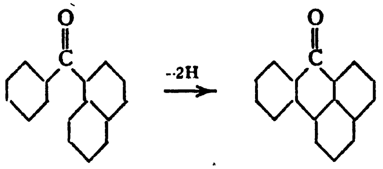
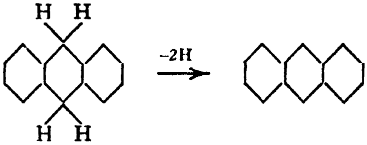
and that phenyl-α-ketonaphthalene was dehydrogenated at 140° C. to yield benzanthrone[68];



Aluminum chloride can also act as a dehydrogenating agent without effecting nuclear condensation. For example, Scholl and Seer[69] have shown that it is possible to obtain anthracene by treating 9,10-dihydroanthracene with aluminum chloride.



A similar dehydrogenation of 9,10-diphenyl-9,10-dihydroanthracene to 9,10-diphenylanthracene has also been shown to take place.[70]

Besides these dehydrogenation reactions, aluminum chloride also causes a rearrangement and splitting off of side chains in certain benzene derivatives. Thus Copisarow[71] observed that when commercial xylene is heated at its boiling point with 3 to 20 per cent of its weight of aluminum chloride about one-half of the xylene is recovered unchanged, toluene is obtained in a yield of about 20 per cent together with a small quantity of benzene, and about 30 per cent of the original xylene is converted into substances of higher boiling points, probably higher homologues of benzene. Lacourt[72] reported that at room temperatures p-ter-butyl-toluene reacts with anhydrous aluminum chloride yielding isobutane, toluene, di- and tri-butyltoluene, some unchanged hydrocarbon and a high-boiling residue. Under the same conditions p-cymene yields benzene, toluene, xylene, 3,5-diisopropyltoluene, unchanged cymene and a high-boiling residue.

INDUSTRIAL APPLICATIONS OF THE POLYMERIZATION OF OLEFINS BY ALUMINUM CHLORIDE AND OTHER HALIDES

Much attention is being directed toward the polymerization of the very abundant supplies of olefins, particularly the gaseous ones, to high molecular weight hydrocarbons, especially with a view to producing synthetic lubricating oils.[73] Otto[74] found, for example, that the oils produced by the action of boron trifluoride on ethylene under pressure have lubricating properties. The work of Stanley (already discussed) on the production of oils from the polymerization of ethylene by anhydrous aluminum chloride is of interest in this connection.

Brownlee[75] produced a low cold-test lubricating oil (pour test, —68° F.) by the polymerization of the liquid olefins in cracked gasolines with anhydrous aluminum chloride. A similar process was proposed by the Braunkohlen Produkte A.-G.[76] Gaseous olefins may also be polymerized by passing them under slight pressure through a suspension of aluminum chloride in gasoline or some other liquid medium at ordinary temperatures.[77] Krauch[78] reported that when gaseous olefins are passed into suspensions of aluminum chloride in petroleum ether polymerization to lubricant hydrocarbons of high molecular weight takes place. When the middle oils are used as the medium, not only do polymerization reactions occur but there is also a condensation between the middle-oil hydrocarbons and the olefins. The result is that from the thin middle oil, highly viscous oils somewhat similar in properties to lubricating oils derived from natural petroleum are produced.

The production of lubricating oils by the polymerization of olefins, particularly those from the cracking of paraffin wax, was described by Sullivan, Voorhees, Neeley and Shankland.[79] Such oils are characterized by high flash point, high specific gravity, relatively small changes in viscosity with temperature, excellent color, low Conradson carbon, and low susceptibility to oxidation. Furthermore, since no wax-like substances are formed during the polymerization process these oils also possess low pour tests. The method[80] of producing such oils may be described briefly as follows: The crude wax is cracked at atmospheric pressure at a temperature of 950° to 1000° F. (510° to 540° C.). A distillate having an end point of about 500° F. (260° C.) is separated from the products of cracking and this is polymerized by stirring with aluminum chloride (50 grams per gallon of distillate) for 18 hours at 210° F. (99° C.). The stirring is then stopped and the tar which settles is withdrawn. The remaining oil is next steamed until the desired viscosity is reached. In one example, the products so obtained consisted of about 10 per cent of light distillate, 80 per cent of an oil of 90 seconds Saybolt viscosity (at 210° F.), and about 10 per cent of tar.

Zherdeva[80a] treated cracked fractions boiling between 150° and 280° C. with 3 per cent aluminum chloride for 30 hours at 60° to 70° C. under atmospheric pressure. Two layers were formed, the upper containing a synthetic oil (amounting to 30 to 40 per cent) of low pour point and good viscosity index. On oxidation with air at 150° C. for 24 hours, carboxylic acids formed.

The products obtained by cracking mineral oils or tars, brown-coal tar oils or petroleum residues may be polymerized in the presence of anhydrous halides, such as aluminum chloride or boron fluoride, to yield lubricating oils.[81] The cracking operation can take place in the presence of metallic catalysts[82] (e.g., porous iron or nickel), or decomposition may be accomplished by first forming the chlorine derivatives of the hydrocarbons and then eliminating hydrogen chloride from these by heating in the presence of aluminum oxide, zinc chloride, or other similar catalysts.[83] Before condensation with aluminum chloride, aromatic hydrocarbons (naphthalene or anthracene) can be mixed with the products described above.

In producing lubricating oils by the polymerization of olefins, the addition of finely divided aluminum, or zinc [84] or nickel [85] to the aluminum chloride, according to Howes, increases its activity. Hagemann [86] reported that the activity of the catalyst is reduced by the presence of oxygen or sulphur compounds.

Weizmann and Legg [87] proposed to polymerize butylene at a temperature of —10° C. in the presence of a catalyst such as aluminum chloride to form naphthene hydrocarbons in quantitative yields. It has also been stated that unsaturated hydrocarbons (isobutylene and amylene) can be polymerized by subjecting them to the action of the addition compounds of aluminum chloride, or other metallic chlorides, and substances other than olefinic hydrocarbons. Examples of such addition compounds are those of aluminum chloride with nitrobenzene, acetone and benzoyl chloride.[88] Haeuber [89] polymerized liquid olefins by heating them in the presence of the addition compound of ethylene and aluminum chloride, prepared by leading ethylene through a suspension of aluminum chloride in a saturated hydrocarbon at 40° to 60° C.

When gases rich in lower olefins such as ethylene, propylene, butylene and amylene, are passed into liquid hydrocarbons containing catalysts of the Friedel-Crafts type (aluminum, zinc, or ferric chlorides), oils which may be used as lubricants are obtained. The activity of the catalysts may be increased by the addition of mercuric or uranyl chloride. Temperatures up to 200° C. are recommended and either atmospheric or higher pressures may be employed.[90] According to Petrov, Antzus and Pozhiltzeva,[91] synthetic lubricating oils from cracking gas and aluminum chloride contain a smaller amount of aromatics when the reaction temperature is low. They also find that the synthetic oils are more homogeneous than natural mineral oils.

The polymerization of mineral and tar oils free from paraffin wax and boiling from 200° C. to 300° C. has been carried out by heating them below cracking temperatures in the presence of anhydrous aluminum chloride and finely divided metals or metalloids. For example, brown-coal tar (100 parts), having a viscosity of 2.8° Engler at 20° C., is stirred with 9 parts of aluminum chloride and 1 part of zinc dust at 180° C. for 8 hours. Copious evolution of hydrogen sulphide takes place but there is no cracking. Lubricating oil (46 per cent by weight) of a viscosity of 24° Engler at 20° C. together with burning oils is obtained.[92] Unsaturated oils from sulphur dioxide extracts of hydrocarbon oils may be polymerized with aluminum chloride below 150° C.[93]

Another process for converting mixtures of hydrocarbons (from the destructive hydrogenation of coal, the cracking of oils, or the low-temperature carbonization of coal) into products of higher boiling points consists of subjecting them to the action of a halogen, or halogen-exchanging substance, and a halide of an element from the third to eighth group of the periodic table.[94] The operation is generally conducted at a temperature below 100° C. As an example, 10 parts of middle oil, with a boiling range of 200° to 270° C., are treated with 1 to 2 parts of chlorinated methanes and 1 part of aluminum chloride at a temperature below 40° C. in a diluent such as benzene. According to a process developed by Chappell,[95] hydrocarbon oils containing naphthenes may be condensed with chlorinated gaseous hydrocarbons in the presence of aluminum chloride. The products are drawn into a second reaction zone where they are treated with more aluminum chloride at a higher temperature; decomposition into gasoline and high-boiling oil is said to take place. A viscous lubricating oil (yield 50 to 60 per cent) can be produced from paraffin wax or hydrocarbons having a mean molecular weight of 170 to 250 in the presence of aluminum chloride and agents such as chlorine, oxygen and sulphur.[96]

According to Thomas and Carmody,[97] who were especially interested in synthetic resins from petroleum hydrocarbons, four reactions appear to take place when a cracked petroleum distillate is treated with aluminum chloride:

(1) Reaction of olefins to form high-boiling oily polymers.
(2) Reaction of olefins with aromatics to form substituted aromatics.
(3) Polymerization of diolefins and olefins to form resins.
(4) Reaction of diolefins with substituted aromatics to form resins.

Reaction 1, while of importance in the production of lubricating oils, is detrimental to resin formation. Such oils, because of their high boiling points, are difficult to separate from the resin, and their presence in the resin reduces its melting point. Such low-melting resins are not generally desirable in the paint and varnish industry.

Reaction 2 does not stop with the monosubstituted compound, and di- and trisubstitutions often take place. These latter substituted aromatics are often high-boiling oils, and therefore the same objections are applicable to them as to the oils resulting from reaction 1.

With reference to reaction 3, Thomas and Carmody[98] have shown that when a pure diolefin is treated with aluminum chloride no apparent reaction takes place, but the addition of an olefin initiates it. For example, isoprene alone does not react with aluminum chloride, but when 2-pentene is added a violent reaction takes place. The reaction can be controlled by adding aluminum chloride slowly until it is complete. Breaking down the aluminum complex yields two polymers, one soluble and the other insoluble in hydrocarbon solvents. The proportion of the soluble polymer formed is a function of the amount of 2-pentene present, and the hardness of the resin varies inversely with this component. The insoluble polymer, having an empirical formula of C_5H_8, begins to depolymerize at about 116° C., is decomposed by strong acids and gives reddish-violet colorations with phenols.

Diolefins react with substituted benzenes (reaction 4) to yield hydrocarbon resins. This reaction is governed both by the number of substituting groups in the benzene nucleus and by their nature. Thus, isoprene reacts very slowly, if at all, with benzene, but much more rapidly with toluene and with xylene. With the three xylenes, the yield of resin is less with the p-compound than with o-xylene; m-xylene is intermediate. Again, when the benzene nucleus contains a substituent group other than methyl, the yield of resin is the greater and its color the lighter, the larger and more branched the group.

Cyclic olefins (which react much more vigorously to yield a harder resin of better character) and diolefins follow the same general course of reaction as their corresponding straight-chain homologues.

Chapter 7

Production of Hydrogen and Carbon by Pyrolysis of Hydrocarbons

The pyrolysis of all hydrocarbons leads ultimately to their resolution into carbon and hydrogen.[1] Methane is the most resistant of all hydrocarbons to heat[2] and is always the most important final product (together with carbon and hydrogen) of their thermal treatment. In the initial stages of heating, each hydrocarbon follows its own individual decomposition reactions, but the final result is always the same, namely, the production of carbon, hydrogen and methane in proportions which gradually approach the equilibrium concentrations at the particular temperature used of the reaction $CH_4 \rightleftarrows C + 2H_2$. The dissociation is endothermic and, accordingly, the extent of decomposition increases rapidly with rise in temperature. The equilibrium concentrations of this reaction have been determined (see Chapter 2) and at atmospheric pressure and various temperatures in the presence of nickel are given in Table 45[3]:

TABLE 45.—*Decomposition of Methane:* $CH_4 \longrightarrow C + 2H_2$.

Temp. ° C.	CH_4	H_2	Temp. ° C.	CH_4	H_2
	—Per Cent—			—Per Cent—	
500	53.4	46.6	900	3.4	96.6
600	29.9	70.1	1000	1.8	98.2
700	14.5	85.5	1100	1.0	99.0
800	6.8	93.2	1200	0.6	99.4

Bone and Coward[4] showed that methane differs from other hydrocarbons in that its decomposition is a surface phenomenon even at temperatures of 1200° C. and probably above, whereas with ethane, ethylene and other hydrocarbons the decomposition takes place throughout the whole mass of gas. However, even under favorable conditions, the rate of decomposition of methane is very slow, Pring[5] finding that heating for 22 hours at 1200° C. or 2 hours at 1500° C. was necessary in order to attain equilibrium in this reaction. The experimental results of Holliday and Exell,[6] on the dissociation of methane at various pressures and temperatures up to 1200° C., suggest a reaction approaching equilibrium but bearing no relation to the true reversible equilibrium. They thought this apparent equilibrium resulted from the deposition not of pure carbon but of a hydrocarbon possessing a vapor pressure greater than that of carbon. Holliday and Exell noticed, as have many other observers, that nickel increases the velocity of reaction enormously.

The various processes for the production of carbon and hydrogen from hydrocarbons differ from one another considerably, the conditions being dependent on the character of the products desired. The carbon initially formed in the pyrolysis of hydrocarbons is converted into the amorphous gray variety if subjected to high temperatures for too long a time.[7] Because of this it is necessary to use various devices to remove the carbon promptly from the reaction zone if carbon black, lampblack and similar types of carbon are the desired products. Moreover, in the production of carbon black it is probably best to employ fairly low temperatures. When harder and coarser forms of carbon are desired, one may use high temperatures and fairly long heating periods, that is, conditions which secure optimum yields of hydrogen from simple thermal decomposition processes.

Various materials (metallic iron, nickel and cobalt) are known to catalyze the formation of carbon and hydrogen in the pyrolysis of hydrocarbons, but, in actual operation, the surfaces of the catalyst soon become covered with a layer of carbon which inhibits the catalytic action.[8] Unless means are provided for removing the carbon deposit, either blowing it out at high gas speeds or burning it off periodically with a current of air or oxygen, the catalyst tends to become ineffective. Much attention has been directed to certain other processes which are capable of being catalyzed efficiently but in which the activity of the contact materials is not vitiated by carbon deposition. Among these are the reactions of methane with steam or carbon dioxide:

$$\begin{aligned} CH_4 + H_2O &\longrightarrow CO + 3H_2 \\ CH_4 + 2H_2O &\longrightarrow CO_2 + 4H_2 \\ CH_4 + CO_2 &\longrightarrow 2CO + 2H_2 \end{aligned}$$

and the partial catalytic oxidation of methane with oxygen at high temperatures:

$$CH_4 + \tfrac{1}{2}O_2 \longrightarrow CO + 2H_2$$

These reactions are discussed fully later (Chapter 10) but it is well to note that they all yield mixtures of hydrogen and oxides of carbon and that the quantity of hydrogen produced by the introduction of steam is greater than that obtained in purely thermal decomposition processes. The manufacture of carbon and hydrogen by the direct pyrolysis of hydrocarbons only is considered in this chapter.

The conditions necessary for the production of relatively high grade carbons appear to be (1) comparatively low temperatures consistent, of course, with sufficient rate of decomposition, but, more particularly, (2) the rapid removal of the carbon from the hot reaction zone before it is converted into the hard gray amorphous variety. The carbon formed in some of the earlier thermal processes was almost valueless, the hydrogen being usually the product desired. For example, in one commercial installation for the thermal decomposition of natural gas, only hydrogen was collected. The carbon black simultaneously produced was grayish in color, contained hard particles, had a high apparent specific gravity, and had only one-fifth the tinting strength of ordinary carbon black. Naphthalene was also present in some samples, thus impairing its utility in the rubber-tire industry. The product found no market although some application was made of it in the formulation of cheap paints.[9]

The very low yields of carbon black (corresponding to about 5 per cent of the total carbon) from its manufacture by the incomplete combustion of natural gas (see Chapter 8) have focussed attention on other possible methods of production. The earlier processes proposed for the thermal decomposition of natural gas were unsuccessful, even though yields as high as 40 per cent of the theoretical carbon were obtained, because of the inferior quality of the product.[10] Since 1922 this difficulty has been overcome to a great extent and carbon blacks made in this way have won a place in the market. The thermal decomposition processes not only yield an increased proportion of carbon but simultaneously produce hydrogen. From 1000 cubic feet of methane it is theoretically possible to obtain 31.82 pounds of carbon and 2000 cubic feet of hydrogen.[11] In one process (Thermatomic), a yield of 7 pounds of carbon is obtained consistently from every thousand cubic feet of natural gas.[12] Most of the early processes described in this chapter appear to have been designed primarily for the production of hydrogen, although it is conceivable that some of them might be modified to yield carbon for special purposes.

Production of Carbon and Hydrogen by Simple Thermal Decomposition

In 1886 McTighe[13] proposed a method for the production of carbon by passing hydrocarbon vapors through a heated retort and separating the carbon in depositing chambers. Later, Purtle and Rowland[14] passed hydrocarbon gases at a pressure of 10 pounds per square inch into a closed retort heated to 800° C. and periodically removed the deposited carbon by means of a scraper.

By decomposing hydrocarbon gas in a retort heated electrically at 1300° to 1800° C. and depositing the liberated carbon on the bottom of the retort, which is maintained at a relatively lower temperature, Snee[15] prevented the coking of the carbon which would otherwise occur at the temperature of decomposition.

To avoid the presence of such impurities as naphthalene, Fernekes[16] produced lampblack from methane or natural gas by passing the gas through an alundum tube heated to a temperature of 1300° to 1700° C. Under these conditions the gas is decomposed into carbon and hydrogen without the formation of intermediate products.

Szarvasy[17] described a process for the production of pure retort carbon by passing methane over pieces of carbon heated to a glowing temperature in an inclined retort. The carbon forms a dense and strongly adherent deposit on the carbon fragments. The carbon particles, whose size is thus increased, are removed either intermittently or continuously, and smaller fresh carbon fragments are introduced to replace them. The heating is effected electrically, or by combustion of methane-air or hydrogen-air mixtures. The heating by combustion and the decomposition reaction may be effected alternately in separate stages in the same retort.

By passing methane through an externally heated chamber composed of previously formed carbon, or carbon fragments, Szarvasy[18] also obtained carbon. Since the incandescent walls of the carbon reaction chamber are efficient surfaces for promoting the dissociation of the methane, carbon-fragment filling may be omitted. As the decomposition proceeds the carbon must be removed periodically, together with the original carbon walls which must be replaced. Part of the resulting material may be used for relining the decomposition chambers and part for the manufacture of carbon electrodes.[19]

By using a mixture of nitrogen and methane in such an operation it is possible to obtain a mixture of hydrogen and nitrogen for the synthesis of ammonia.[20]

Szarvasy and Bensel[21] suggested making soot carbon, retort graphite and similar products from natural gas by continuously passing the gas through a heated retort. A yield of 65 per cent carbon is thus obtained and the hydrogen produced simultaneously can be used for heating the retort or for other purposes. Szarvasy[22] also proposed conducting natural gas or other hydrocarbon gas into a chamber maintained at a temperature at which decomposition of the gas occurs. The reaction chamber has walls with holes blocked by a porous carbon deposit or other pervious material and is heated, at least in part, by combustible gases passing through the walls and burning in immediate proximity to them.

Bunte[23] investigated the decomposition of coal gas by passing it through porcelain tubes, both unpacked and packed with iron filings or coke. The gas produced at a temperature of 1100° to 1200° C. had no illuminating value but showed an increased volume and higher hydrogen content. The laboratory studies of Bunte were later extended by von Oechelhaeuser[24] to the production of the so-called "Dessau balloon gas," containing 80.7 to 84.1 per cent hydrogen, 5 to 7 per cent methane, 5.1 per cent nitrogen, and 7.3 per cent carbon monoxide. For this purpose he passed coal gas at 1200° C. over finely granulated coke in common horizontal gas retorts. The carbon produced simultaneously was obtained in two forms, as a finely divided carbon black and as silver-gray crystalline needles.

The Rincker-Wolter Process.

Rincker and Wolter[25] produced hydrogen from oils and tars by thermal decomposition in two generators, somewhat resembling water-gas generators, charged with coke and arranged either one above the other or side by side. After the first generator is heated to incandescence by an air blast, tar is introduced and partly converted into gas by contact with the glowing coke. This gas escapes by expansion. A current of air is then introduced and carries the remaining tar vapors into the second generator where more complete gasification takes place. At the same time this air blow raises the coke in the first generator to incandescence. The process is then reversed; tar is introduced into the second generator and the tar vapors and gas are carried with the blast of air into the first generator.

For hydrogen production by this process the coke bed must be maintained at a temperature of about 1200° C., since too low a temperature yields a gas so poor in hydrogen that subsequent purification is not commercially feasible. At the end of the blowing run, oil is sprayed onto the hot coke for several minutes and this is followed by a current of steam to clear the sprayer. The gases formed by the decomposition pass through water seals to scrubbers and purifiers. By careful working it is possible to obtain a gas containing 96 per cent hydrogen, 1.3 per cent nitrogen, and 2.7 per cent carbon monoxide. The nitrogen content is somewhat reduced by passing this gas over heated soda-lime.[26] To avoid clinkering of the ash of the fuel, Ellis [27] proposed the addition of a small proportion of lime to the coke to flux the ash and thus maintain the requisite fuel-bed temperature.

In a modification of the Rincker-Wolter process,[28] the conversion of liquid hydrocarbons into oil gas is effected by contact with glowing coal or coke in the normal way, and gases containing hydrogen (water gas) are introduced into the oil-gas generator to convert the oil residues into gasified hydrocarbons. This also avoids the formation of tar in the oil-gas generator. Two units are employed, functioning as water-gas generator and oil-gas generator, alternately. A portable plant of the Rincker-Wolter type mounted on two ordinary railway flat cars was used for the production of hydrogen for military purposes.[29] Processes similar to the Rincker-Wolter have been described by Frasch,[30] Lowe,[31] and Thorssell.[32]

Geisenberger [33] generated hydrogen by decomposing low-boiling hydrocarbons such as benzine or other organic materials (bitumen, shale, beeswax, or turpentine) with heat.

Brunner [34] described a process in which natural gas, crude petroleum or garbage grease was converted into hydrogen by passing the gas through a furnace and then through a series of vertical standpipes (connected at top and bottom) through which water is sprayed to remove carbon and other impurities.

A gas of high hydrogen content has been produced by the Berlin-Anhaltische Maschinenbau-A.-G. [35] from coal gas by a process similar to the Rincker-Wolter. Illuminating gas is first freed from carbon dioxide and is then conducted over white-hot coke, yielding a mixture consisting almost entirely of hydrogen, carbon monoxide and nitrogen. The carbon monoxide is removed by treatment with soda-lime and the resulting hydrogen-nitrogen mixture is said to be well adapted for many technical purposes. This process was the subject of exhaustive tests carried out by Weaver.[36] The method, as before stated, consists essentially of a decomposition of hydrocarbon oil by passage of the vapors over surfaces sufficiently hot to decompose the hydrocarbons completely into their elements. In carrying this out a blast of air is blown through a bed of coke to heat it to incandescence in the usual way. The resulting "blast gas" is then burned in a tower filled with checkerbrick, called the vaporizer. When both coke and brick have attained the desired temperature, the oil is vaporized and the resulting vapors are allowed to pass first through the column of brick and then through the hot coke. The carbon deposited in both chambers is burned out during the next air blow and provides part of the fuel necessary for maintaining the required temperature.

In preparing hydrogen from crude petroleum or petroleum tar oils, Pictet [37] proposed to heat the vapors in such a manner that 18.1 calories are supplied to each 16 grams of gas passed through a tube at a temperature of 1200° to 1350° C. Similarly, hydrocarbons such as petroleum vapors mixed with steam may be converted into a mixture of carbon monoxide and hydrogen.[38] By admitting a regulated quantity of oxygen, Pictet [39] found that its combination with the hydrocarbon material can likewise be made to yield sufficient heat to carry on the reaction.

Nauss [40] proposed to obtain hydrogen from coal gas by first converting its carbon monoxide content into methane by catalytic reduction and then subjecting the resulting gas to decomposition at 1000° to 1200° C. in retorts containing coke, charcoal, or clay, impregnated with nickel, cobalt or iron.

The Thermatomic Process.

Undoubtedly the most important of the methods developed for making carbon black by thermal decomposition is the so-called Thermatomic process,[41] the basic ideas of which have been described by Brownlee and Uhlinger.[42] The process consists in heating a furnace lined with refractory brick and filled with checkerbrick to incandescence by an upward blast of natural gas and air, shutting off the air and allowing the natural gas (admitted from the top at this stage), to decompose. The intermittent heating and cracking processes (the latter being endothermic) are carried out alternately. Approximately two-thirds of the total quantity of carbon black produced is formed by impingement against the refrac-

FIG. 19.—General Arrangement of Plant for Thermal Decomposition of Hydrocarbons. (Thermatomic Process.)

tory material or comes into contact with it after formation. Such carbon is valueless commercially and is left in the furnace to be consumed in the next air blow. It is stated[43] that the most desirable operating temperature for the cracking process is 1200° to 1400° C. and the mixture of hydrocarbon and resulting gases, together with the carbon produced, is subjected to these temperatures for a period of 3 to 4 seconds only.

On issuing rapidly from the furnace, the mixture of gases and carbon is passed through a cooling chamber where just enough water is sprayed countercurrent to the gas stream[44] to cool the smoke to a safe temperature for filtering through cloth bags without leaving an excess to wet either the bags or the carbon. The appended diagram (Fig. 19), which is largely self-explanatory, shows the form of apparatus which has been developed, consisting essentially of two cracking furnaces, two coolers, and one collector. Moore[45] gave the typical analyses shown in Table 46 of the natural gas being used and the resultant gas obtained in this process:

TABLE 46.—*Thermatomic Process Gas Analyses, Per Cent by Volume.*

	Natural Gas	Resultant Gas
Carbon dioxide	0.4	0.9
Illuminants	0.7	1.3
Hydrogen	—	85.4
Carbon monoxide	—	1.1
Methane	93.8	5.0
Nitrogen	5.1	6.3

This process has been producing the carbon called "Thermax" since 1922. Another brand, called "P-33," which is blacker and finer than Thermax and was put on the market later, is made in the same way as Thermax, except that a portion of the resulting gas is recirculated and acts as a diluent for the decomposing natural gas. This dilution principle is so effective that it reduces the average particle size to about one-fifth that of Thermax.[46] A comparison of the physical and chemical properties of these two carbons, as reported by Moore,[47] is given in Table 47.

TABLE 47.—*Properties of Thermatomic Carbons.*

	Thermax	P-33
Specific gravity	1.80	1.80
Apparent gravity (kg./cu. meter)	481.5	356.1
Tinting strength[a]	14%	50%
Average particle size	1.0 micron	0.23 micron
Moisture	0.25%	0.25%
Ash	0.05%	0.15%
Benzene extract (16 hrs. extraction)	0.60%	1.25%

[a] The standard for these tinting strength percentages was Cabot's channel black.

Passing natural gas, previously freed from hydrogen sulphide, through a furnace filled with incandescent coke or refractory material for the production of hydrogen was proposed by Frank.[48] The decomposition of the gas begins at

[48] U. S. Patent 1,107,926, Aug. 18, 1914; *Chem. Abs.*, 1914, 8, 3359. See Ellis, "Hydrogenation of Organic Substances," D. Van Nostrand Co., New York, 1930, 768.

800° C. but complete decomposition into its elements is not obtained below 1200° C. In a similar way Rose[49] prepared a gas containing as much as 98 per cent of hydrogen by conducting natural gas or oil vapors over refractory materials heated to 1650° C.[50] Herman[51] produced soot and hydrogen from light hydrocarbons, especially natural gas, by contact with highly heated refractory surfaces against which the gas is allowed to impinge in a number of finely divided currents. Pyzel[51a] substantially confines the decomposition to fractions heavier than methane by regulating the rate of gas flow and the temperature of the refractory material. The resulting gas is purified and fractionated, the undesired compounds obtained thereby being used to heat the refractory material. The heat of the cracked products is also utilized by injecting into the hot gas stream at various points, further quantities of the gas to be treated.[51b]

The process of Bacon, Brooks and Clark[52] for the production of carbon black and practically pure hydrogen from hydrocarbons was devised to insure a satisfactory yield of both products in continuous operation. It is conducted in such a manner that the particles of carbon black remain suspended in the hydrogen and are thus rapidly removed from the reaction zone, thereby avoiding deterioration of the carbon from continued heat treatment. The temperature of decomposition is maintained above 1200° C. and the rate of feed of the hydrocarbon is so adjusted that the gas velocity developed is sufficient to sweep the carbon particles from the reaction zone. Substantially pure hydrogen is obtained and the recovered carbon black has a silky luster.

Ellis[53] has described a furnace connected to a brick checkerwork chamber which may be used for the thermal treatment of hydrocarbons to yield hydrogen. Hydrocarbon oil is introduced above a bed of coke heated to a white heat and the resulting vapors are passed through the heated checkerwork where further decomposition occurs. The furnace is provided with air and steam inlet pipes for blowing up the fire and for sweeping out the gases.

In another process McCourt and Ellis[54] obtained carbon and hydrogen by forcing methane through a highly heated porous bed of refractory material at such a speed that the carbon particles are removed from the hot reaction zone.

To produce hydrogen Barth[55] decomposed liquid fuels (oils or tars) in a furnace and subjected the gaseous products of the decomposition to a further thermal treatment in a separate furnace. It is stated that by this method of operation, there is an economical use of fuel and the contact mass on which hydrogen formation proceeds does not become contaminated with carbon. The furnace or vaporization chamber is an iron jacket lined with firebrick and filled with a refractory grating or with coarse pieces of refractory material. The combustion gases escaping from the generator during the blow-period are passed through the refractory grating of the vaporization chamber. Near the end of the blow-period the gas contains carbon monoxide and this is burned within the vaporization chamber after the admission of air. In this way the heat necessary for vaporizing the liquid fuel is provided. After the air supply is shut off, the vaporized oil is passed into the vaporization chamber and thence through the glowing charge of coke in the generator. The coke is maintained at about 1000° C. if illuminating gas is to be made, but a higher temperature is necessary for the production of hydrogen. The oil vapors are passed through the generator alternately in opposite directions, that is, first from above and then from below.

Snelling[56] proposed to heat organic compounds capable of reversible thermal dissociation in a closed chamber, the walls of which are more permeable to hydrogen than to other substances. The hydrogen formed is withdrawn through the permeable walls during the reaction. Battig[57] produced hydrogen from methane or other hydrocarbons by passing them successively through a preheated chamber containing a latticework of bricks, an apparatus heated to the temperature necessary for decomposition, a chamber in which carbon is deposited, and a cooling chamber also packed with bricks. When the last chamber becomes unduly heated, the supply of gas is shut off and air or oxygen is passed through the apparatus in the reverse direction to burn away the carbon and to reheat the preheating chamber. The carbon may be deposited on coke, iron, or on ores for subsequent smelting. Steam and oxygen may also be used in the decomposition to produce carbon dioxide and hydrogen.[58] A similar process has been described by Vinther.[59] The carbon which deposits on the refractory during the decomposition is burned to carbon monoxide, which is then burned to preheat a second chamber, thus rendering the process cyclic and independent of an external fuel supply.

Nelson[60] proposed to make refined lampblack by decomposing hydrocarbon oils at 500° to 700° C. in the absence of air. The liberated carbon is collected in a condensing chamber (maintained at 400° C.) and the gases pass on and are condensed, the non-condensible substances being used later to heat the apparatus. To remove the last traces of volatile matter from the carbon a current of hot gas (e.g., that obtained in the process) may be passed over it.

Burwell[61] described the production of hydrogen and carbon of good quality by the thermal decomposition of hydrocarbons. In his process a stream of natural gas or vaporized petroleum hydrocarbon preheated to a temperature just short of decomposition (about 150° to 450° C.) is mixed with a diluent (hydrogen) heated to 1200° to 1300° C. This mixture is allowed to remain in a heated zone until substantially complete decomposition of the hydrocarbon material is effected. The products are then passed to a cool settling chamber where the carbon separates. The resulting gas, consisting largely of hydrogen, is divided into two portions, the major portion being retained in the closed circuit (i.e., used as a gaseous diluent for further decomposition of hydrocarbon material), and the remainder withdrawn for purification. By varying the hydrocarbon raw material and the ratio of the gaseous diluent to gaseous decomposition products in the mixture, the quality of the carbon produced can be changed. A similar process has been proposed by Day.[62] Burwell[63] obtained hydrogen containing 0.2 per cent methane and 0.7 per cent carbon monoxide by passing a hydrocarbon oil through two retorts, the first heated at 950° to 1000° C., and the second at 1140° to 1170° C., with settling chambers after each for the removal of carbon black. A similar method of using two heating chambers with one expansion chamber was proposed by Fischer[64] for the manufacture of lampblack.

Finely divided carbon and a mixture of hydrogen and nitrogen in the ratio of 3 to 1 are obtained by Wilcox[64a] in the following manner. An active combustion of fuel gas takes place in the retort. The fuel gas passes countercurrent to the hydrocarbon gas and air, maintaining thereby a temperature of about 1100° C. The nitrogen and hydrogen produced may be used in the synthesis of ammonia. In Burke's[64b] method for the production of carbon black, gaseous hydrocarbons diffuse into a stream of highly heated gas. The flow of gas is maintained in a non-turbulent stream. Preheated natural gas may be subjected first to a cracking temperature and the cracked stock passed through a series of chambers.[64c] Each of these chambers has a temperature lower than the cracking temperature and contains cool hydrogen. The gas thus undergoes a "shocking" treatment, carbon black being recovered from the "shocked" stock.

On passing methane preheated to 800° C. through a vertical graphite or carborundum tube, Padovani[64d] obtained higher hydrocarbons along with carbon and hydrogen. The tube was heated to 1000° to 1300° C., and was so dimensioned that the ratio of area of contact (square centimeters) to volume (cubic centimeters) was 0.25 to 1. The heating period was 0.5 to 6 seconds and the pressure was approximately 1 atmosphere.

The distribution of the products of the thermal decomposition of a hydrocarbon gas in a cool inert gas to collect and separate them was described by Lewis.[65]

A process for making carbon in which vapors of hydrocarbons are passed at such a rate through a bed of incandescent coke maintained at 1000° to 1200° C. that the gases emerge at a temperature of 600° to 700° C., has also been suggested.[66] The carbon formed is swept out of the reaction chamber by the gaseous products.

In another process hydrocarbon vapors pass through a mass of ignited fuel and are converted into carbon, hydrogen and methane.[67] The temperature of the fuel is so regulated that the methane in the hydrocarbon gases, as well as that formed by decomposition of the higher hydrocarbons, is decomposed by contact with the surface of the fuel and all the carbon liberated is retained on the surfaces of the fuel. According to Perry,[68] the hydrocarbons may be separated from the gas and used again. The fuel bed may be treated with steam to decompose the deposited carbon with the production of water gas, from which more hydrogen is recoverable. The hydrocarbons and steam may also be passed through the fuel bed simultaneously.

In the procedure developed by Hillhouse,[68a] a shower of incandescent carbon is allowed to fall through the gas. An axial flame is maintained in the chamber and serves to heat the carbon.

Lewis[69] obtained a mixture containing 15 to 70 per cent hydrogen by passing natural gas, stripped of its heavier constituents, through a tube heated at 600° to 900° C. At this temperature no free carbon is formed. The cyclic hydrocarbons produced in this pyrolysis may be removed by condensation. The gas may be burned to yield carbon black (see Chapter 8).

Garner[70] decomposes natural gas thermally to yield a gas of low calorific value and carbon black. For use as a fuel, the gas resulting from the decomposition is mixed with untreated natural gas in such proportions that the higher calorific value is obtained.

For drying carbon black, the use of the combustible gases formed in the pyrolysis has been suggested.[71]

Other processes for the decomposition of methane or natural gas have been developed by the Ruhrchemie A.-G. and by the Bataafsche Petroleum Maatschappij. In the former[72] the gas is heated at 900° to 1200° C., producing a gaseous mixture containing up to 60 per cent hydrogen which can be used for the autogeneous welding of metals. In the latter[73] the hydrocarbon mixture is heated in a vessel resembling a blast-furnace stove, and after cooling, the resulting gas is scrubbed to remove lampblack, tar, and naphthalene. The hydrogen can be separated from the other gaseous products (ethylene or propylene) by fractionation (see Chapter 4). The cracking of natural gas in water-gas generators to produce carbon black and gases rich in hydrogen was investigated by Odell.[74]

Carbon having the crystalline structure of graphite was obtained by Hofmann and Groll[75] by dropping benzene (boiling at 60° to 70° C.) from a capillary through a vertical quartz tube heated to 950° C.

Carbon and hydrocyanic acid, according to Poindexter,[76] are the products of heating a mixture of ammonia and natural gas, kerosene vapor or other hydrocarbon material.

DECOMPOSITION EFFECTED BY PARTIAL COMBUSTION OF HYDROCARBONS

In many of the methods thus far described, the heat required for the reaction is obtained from some external source or from an incandescent fuel bed and in others the temperature is maintained by combustion of the deposited carbon. The thermal conditions necessary for the decomposition may be secured by partial combustion of some of the hydrocarbon material itself, the basis of a number of processes. Carbon monoxide, one of the products of the combustion, is itself capable of decomposing or of burning to carbon dioxide and brief mention of a few processes in which this occurs is also included in the discussion. Another larger and better-known group of methods in which incomplete combustion of some of the hydrocarbon material maintains the decomposition temperature is discussed in Chapter 8, where deposition of carbon from flames is considered. This, too, is apparently a purely thermal decomposition induced by the heat of combustion of a portion of the hydrocarbon supply. It is perhaps well to anticipate also at this point two other means of maintaining the temperature required to effect decomposition which will be discussed later, namely, the electric arc and metallic baths maintained at high temperature.

[76] U. S. Patent 1,562,914, Nov. 24, 1925; *Chem. Abs.*, 1926, **20**, 481.

Frost and Nix[77] proposed the manufacture of gases and carbon black by the incomplete combustion of petroleum vapor in a closed chamber. Darrah[78] introduced fuel oil into a current of heated gases containing insufficient oxygen for complete combustion to obtain a high grade lampblack. Poindexter,[79] to prepare a carbon pigment, heated natural gas to a temperature slightly below the point of decomposition and then mixed it with air at a higher temperature in an amount insufficient for complete combustion.

The oxidation of methane or its homologues with air or oxygen, and carbon dioxide has been used by Bradley[80] in making lampblack. The reacting gases are mixed in such proportions and at such temperatures, that enough additional heat is generated by the exothermic oxidation of the hydrocarbon to compensate for that consumed by the endothermic reaction of the carbon dioxide with the hydrocarbon. The carbon monoxide produced in the reaction is converted to carbon dioxide, which is then separated and utilized again. Goodwin[81] mixed air and a hydrocarbon gas or vapor in a reaction chamber, heated to a temperature above the maximum attainable by combustion of the mixture, to produce finely divided carbon. Lewis[81a] partially burned hydrocarbons and allowed the flames to impinge on metallic surfaces, obtaining a deposit of carbon black.

The reduction of carbon monoxide or dioxide by finely divided carbon has also been proposed as a method of manufacture of carbon black.[82]

A process of producing carbon black described by Matlock[83] consists in burning hydrocarbon gases in a furnace with a regulated supply of air. On passing upward through the furnace the gas and air mixture encounters a zone of burning gases. After cooling the resulting gaseous product, the carbon is separated. Bone[84] obtained hydrogen by using a proportion of oxygen or air with the hydrocarbon gas large enough to avoid deposition of carbon and passing the gaseous products over coke at a temperature of 1200° C. Steam may be added and austenitic steels or silica may be used for the apparatus. A similar process has also been proposed by the I. G. Farbenindustrie A.-G.[85]

Carbon monoxide has received some consideration as a possible source of finely divided carbon on account of the ease with which it decomposes into free carbon and carbon dioxide in the presence of metallic catalysts at temperatures of about 300° C. and over, according to the reaction:[86]

$$2CO \longrightarrow C + CO_2$$

An excellent account of the decarbonization of carbon monoxide is given by Marek and Hahn, "Catalytic Oxidation of Organic Compounds in the Vapor Phase," Chemical Catalog Co., Inc., New York, 1932, 108.

Processes have been described for the production of a finely divided carbon by decomposing carbon monoxide at 600° to 1000° C. in the presence of iron or iron oxide.[87] Other catalysts (nickel or cobalt and their oxides) have also been proposed.[88] A vaporized carbonyl of a metal of the iron group was proposed as a catalyst for this reaction by Kramer and Bub[89] and by Haag.[90] The reaction is carried out at about 400° C. under 100 atmospheres pressure. Grosskinsky[91] prepared lampblack by splitting carbon monoxide or hydrocarbons using as catalysts, metals or oxides of the iron group obtained by decomposition of compounds other than their carbonyls.

DECOMPOSITION EFFECTED IN THE ELECTRIC ARC

The decomposition of gaseous and liquid hydrocarbons by the electric arc is discussed in Chapter 9. Several such methods, however, in which carbon and hydrogen are produced by the decomposition follow.

Winkler[92] observed the formation of carbon and non-condensible gases from heavy California oils by the action of an electric arc (Birkeland-Eyde) in hydrogen. By passing an electric arc between carbon electrodes immersed in various organic liquids contained in an ice-cooled flask, Tarczynski[93] obtained precipitated and colloidal carbon.

Hutchins[94] proposed a process in which a film of tar or oil on a revolving carbon or graphite disc is subjected to the action of one or more electric arcs in an air-tight casing. The gas and lampblack are drawn off through a pipe by a fan. The lampblack is separated by a filter and part of the gas is drawn off and part is returned for further treatment. Instead of the electric arc, one or more oxyhydrogen, oxyacetylene, or other high-temperature gas flames may be used.[95]

Jakowsky[96] made a study of electrical methods of manufacturing carbon black. Attempts to dissociate natural gas with various types of nitrogen-fixation apparatus ("spreading arc") were made, but the experiments indicated these methods to be impracticable. Both an intermittent and a continuous type apparatus, however, gave considerable proportions of carbon, which caused short-circuiting of the electrodes and lead-in tubes, as it formed in a fluffy deposit. By washing out the carbon with water or oil as formed, this difficulty was overcome and the apparatus thus modified worked satisfactorily in continuous operation.[97] The effects of pressure, enriching the gas with gasoline, use of high-frequency current, and passing the gas and arc through apertures in mica discs were investigated. The decomposition of liquid hydrocarbons was also effected in such an apparatus. Lower voltages and higher currents could be used with oil. It was found that oxygen compounds such as creosote broke down more easily than paraffins but they tended to form pitch and gummy residues. Carbon black obtained by such electrical processes compared favorably with the better grades of the commercial product both in tinting strength and particle size. Unlike ordinary commercial black, it does not tend to agglomerate when dispersed in oil. The non-condensible gases formed in the electrical production of carbon black from oils contain approximately 10 per cent methane, 50 per cent hydrogen and 35 per cent unsaturated hydrocarbons. The manufacture of alcohols from these unsaturated hydrocarbons (see Chapter 11) was considered. In their experiments on the decomposition of methane in the high-tension arc, Stanley and Nash [98] also obtained up to 20 per cent of finely divided carbon and a gas containing up to 14 per cent acetylene and 2 per cent ethylene.

Hydrogen is also produced by passing hydrocarbons through an electric arc. A gas containing 14 per cent methane and 86 per cent hydrogen, for example,[99] may be treated in this way to obtain a gas containing 7 per cent acetylene and 93 per cent hydrogen. Coke-oven or natural gas may be converted to a gas consisting almost entirely of hydrogen by a similar process.[100] Bethenod [101] effected decomposition by immersing high-fusing conductors heated to above 800° C. in the liquid under treatment. By this method, anthracene oil can be made to yield hydrogen and acetylene.

Eisenhut [102] proposed to make carbon, hydrogen, and acetylene by subjecting hydrocarbon vapors under pressure to the action of an electric arc at temperatures above 2500° C. Hydrocarbons such as methane are passed through the arc at such a rate that the ratio of the rate in cubic meters per hour to the power of the arc in kilowatts is below 0.6. The gases containing the soot can be directed into a cooled chamber and the lampblack separated by cooling in stages.[103]

Processes for the purification of carbon black generally involve heating the black to temperatures high enough to drive off volatile hydrocarbons. For example, the carbon obtained by the action of an electric arc on a hydrocarbon oil can be freed from water and unchanged oil by heating at 350° to 400° C., according to Gobert.[104]

DECOMPOSITION EFFECTED IN BATHS OF MOLTEN METALS

Lampblack and hydrogen were obtained by Masson[105] by passing a combustible mixture of air and methane, or other hydrocarbons, through a bath of molten magnesium, copper, silver, nickel or slag maintained at a temperature of 1100° C. (2000° F.). In passing through the bath, the hydrocarbon is dissociated into its elements and the carbon as formed is blown out by the hydrogen. On leaving the bath, the reaction products are cooled as quickly as possible to 120° C. (250° F.) and the lampblack is precipitated, in order to produce a soft and fluffy product. The hydrogen can be used as a fuel to maintain the temperature of the bath. Paris,[106] on the other hand, suggested the use of a metal of lower melting point, such as lead. On leading the hydrocarbon vapors through the mass of molten lead the lampblack formed floats on the surface of the liquid and is removed by a stream of gas. Bähr[107] proposed the use of fused iron and fused copper at 1300° C. in a similar process.

For producing hydrogen, methane is blown into a bath of molten iron at a temperature of 1200° to 1300° C. in a method described by Tyrer.[108] The carbon liberated by the decomposition dissolves in the iron and is subsequently removed by blowing with air or a gas containing oxygen. Alternatively, the methane and air can be blown continuously into opposite ends of a reaction chamber provided with a partition dipping below the surface of the iron to prevent mixing of the gaseous products in the two sections. Additional air may be admitted above the iron in the oxidation section to oxidize the carbon monoxide formed. A catalyst (nickel) may be added to the iron bath, together with manganese to increase the solubility of the catalyst and the carbon in the iron. Steam may also be mixed with the methane.

CARBON AND HYDROGEN FROM ACETYLENE

The explosive nature of mixtures of air and hydrocarbons is well known.[109] Any mixture with air containing from 3 to 82 per cent of acetylene, for example, is explosive.[110] Most hydrocarbons require a high temperature for decomposition into carbon and hydrogen, as pointed out previously. This is because the dissociation reaction is endothermic, that is, non-explosive. However, acetylene is an exception. Heated at moderately high temperatures without oxygen it undergoes an exothermic (explosive) dissociation into carbon and hydrogen. Rimarski[111] found that pure acetylene decomposes spontaneously in the presence of iron surfaces heated to 510° C. at a pressure of 2.05 atmospheres. Below this temperature, even on raising the pressure, no indication of explosive decomposition was observed. The effect of other metals and metal powders in promoting this explosive decomposition was also studied by Rimarski and Konschak.[112] Acetylene is slowly decomposed at 180° C. by iron, cobalt, nickel and silver powders, and at 200° C. by copper powder. Copper decomposes acetylene with explosive violence at 460° C., but with ferric oxide, cupric oxide and manganese oxide (Mn_3O_4), the temperature need be no higher than 240° to 310° C. Such substances as aluminum oxide, silicon dioxide and active carbon also promote explosion at these temperatures.

The decomposition of hydrocarbons, especially acetylene, with or without air, has been used to make a special quality of carbon black. This black, usually referred to as acetylene black, is very soft and fluffy and has an inherent bluish tinge which makes it desirable for some purposes.[113] Refuse calcium carbide, such as a grade too finely divided or having too low a content of carbide to be marketable, is a source of acetylene for conversion to this by-product black. Neal[114] stated that a carbon made by burning acetylene (see Chapter 8) is of better color than that made by explosion.[114a]

Hubou[115] produced acetylene black and hydrogen by exploding acetylene in a closed vessel in the absence of air by an incandescent tube or wire or by an electric spark. Frank[116] decomposed a mixture of acetylene and carbon monoxide or dioxide to produce a carbon free from tarry condensation products.

In the process used by Machtolf,[117] acetylene under pressures of up to about 6 atmospheres was exploded by an electric spark to produce hydrogen and lampblack. Mixtures of hydrocarbons with oxides of carbon or other gases, which cannot be exploded at ordinary temperature and under pressure, have been found by Gollmert[118] to explode if heated and to yield finely divided carbon. Combustion of a mixture consisting of acetylene, an indifferent gas and a metal carbonyl can be provoked by a single short charge of energy, a method proposed for the production of carbon.[119] Other methods of exploding or otherwise decomposing acetylene by heat have been suggested by Morehead,[120] Pictet,[121] Wegelin,[122] and Bosch.[123] Pictet[124] proposed to decompose hydrocarbons containing acetylene in a tube, the first portion of which was heated to about 500° C. At this temperature acetylene decomposes into its elements with a considerable evolution of heat, which renders the continuous decomposition independent of external heat. In like manner Waterman and Tulleners[124a] decompose ethylene

explosively, by heating in an autoclave at 350° C. under a pressure of about 170 atmospheres.

Apparatus for the explosive decomposition of acetylene has been described by Machtolf[125] and by the Hydrocarbon A.-G. für Chemische Produkte.[126] Rimarski and his co-workers[127] reported that detonation must be avoided in the commercial manufacture of acetylene black. This is done by holding pressures at or below a definite low starting pressure or by diluting acetylene with a gas such as hydrogen or oil gas.

DECOMPOSITION EFFECTED IN THE PRESENCE OF CATALYSTS

With catalysts the thermal decomposition of hydrocarbons to carbon and hydrogen can be effected at somewhat lower temperatures than those ordinarily required. Cantelo[128] studied the thermal decomposition of methane in the presence of silica gel, manganese dioxide, calcium oxide, bone black, and mixtures of copper and copper oxide, nickel and nickel oxide, and iron and ferric oxide, and suggested the use of such catalysts to lower reaction temperatures to improve the quality of the black produced. As pointed out previously, the activity of catalysts is impaired when carbon is deposited on their surfaces, and therefore some provision must be made for its removal or for preventing its deposition.

An investigation of the decomposition of a kerosene fraction, boiling from 200° to 230° C., by passing its vapors over heated pumice impregnated with metallic cobalt, iron, nickel and manganese was made by Kanning and Brown.[129] They noted that the catalyst was poisoned by carbon deposited at low temperatures, although no such effect was observed at high temperatures. The ability of these catalysts to decompose kerosene vapors decreases in the order given. Cobalt was effective as a catalyst for continuous conversion at temperatures above 500° C. Increasing the temperature increased the proportion of hydrogen in the gaseous products and decreased the proportion of methane. Although in all cases increasing the temperature increased the decomposition of the kerosene vapors, at higher temperatures an increase was noted in the percentage of hydrogen in the gaseous products in the presence of cobalt and nickel. Under similar conditions with iron and manganese catalysts the percentage of methane was increased. When a nickel catalyst was used a relatively large percentage of unsaturated hydrocarbons was formed in contrast to only traces with cobalt. With both nickel and manganese large quantities of paraffin hydrocarbons other than methane were also formed. In the presence of iron at 400° C. the gas contained the largest percentage of hydrogen (90.5 per cent) and with nickel at 390° C. it had the greatest percentage of methane (46.4 per cent).

In the decomposition of hydrocarbons at temperatures below 1000° C., the formation of soot may be avoided by using two catalysts of different powers.[129a] The gas is led over the less active catalyst first, and hydrogen and higher hydrocarbons are produced.

Good yields of carbon black were obtained by Bancroft[130] by decomposing methane at 1200° C. or higher. In his process the hydrocarbon gas is passed between the concave bottom of a flame-heated combustion chamber and a rotating steam- or water-cooled drum, the surface of which is parallel with the hot surface of the combustion chamber. The heating surface may be composed of copper, nickel, or other materials exerting a catalytic effect. The carbon formed is subjected to a high temperature for only a short time, being quickly removed from the cracking zone and scraped from the rotating drum.

Crommett, Hawkins and Wheelock[131] passed methane or other hydrocarbon gases through a tube lined with palladium, nickel, manganese, or a similar metallic catalyst and heated externally to about 700° C. The carbon black formed in good yield is pushed out of the tube at regular intervals by a ram. The temperature of the catalyst should be varied somewhat (for example, between a temperature of 700° and 750° C. with palladium) by providing a secondary varying source of heat.

For the decomposition of unsaturated hydrocarbons (ethylene, acetylene and diacetylene) to produce carbon black the use of a metal of the iron group (nickel or cobalt) or its oxide has been suggested as a dehydrogenating catalyst by Schmidt and Grosskinsky.[132] The hydrocarbons are treated at a temperature of 300° to 450° C. under a pressure of 30 to 100 atmospheres. The reaction may be effected similarly under reduced pressure[133] and in the presence of other gases such as hydrogen, water vapor, oxides of carbon, and methane. Activators (alkali or alkaline-earth metals or oxides of zinc, cadmium, copper, chromium, vanadium, molybdenum, uranium, or alkalies) may be used with the catalyst.[134] The deposition of iron or nickel catalysts on supports such as charcoal or magnesium oxide for use in the catalytic decomposition of methane into carbon and hydrogen was suggested by Grünstein.[135]

Haag, Schlecht and Schubardt[136] employed a metal carbonyl in effecting the dehydrogenation of olefins and diolefins to carbon black. A catalyst composed of nickel or iron (prepared by decomposing a carbonyl compound) and an alkali metal compound, such as potassium carbonate, was proposed by Haag.[137] Other suggested catalysts include a mixture of at least two solid oxides which are not reduced to metals in the process.[138] Such mixtures may be made from the oxides of aluminum, boron, zirconium, silicon, cerium, thorium, and the alkaline earths. The decomposition can also be effected in the presence of mixtures of metallic oxides of the iron group with acid-forming oxides of metals of groups IV, V, or VI of the periodic system or the compounds formed between oxides of metals of these two types (nickel vanadate) may be substituted.[139]

Since the efficiency of catalysts decreases as they become coated with carbon, they may be allowed to fall through the heated gas stream.[140] The deposition of carbon on any particular particle is thus minimized and fresh catalyst is always present. The catalysts may be readily separated from the carbon, for example, by flotation, magnetic separation or solution in an acid. To overcome this decreasing efficiency it has been proposed to use the catalysts in the form of balls or cylinders which roll freely in a rotating furnace and which by this continuous motion remove the sooty deposit from the active surface.[141] Decomposition may also be conducted in a non-sparking electric field in the presence of these catalysts.[142]

In the catalytic decomposition of hydrocarbons lining the reaction chamber with materials which produce no appreciable decomposition (silver, copper, chromium, or their alloys, or ferrosilicon) has been proposed to prevent clogging of the apparatus.[143]

Decomposition Effected with Chlorine and Chlorine Compounds

A number of methods of making carbon in which a hydrocarbon is treated with chlorine or a chlorine compound have been advanced.[143a] Thus, Averill[144] burned natural gas in an atmosphere of chlorine, forming hydrogen chloride and lampblack. Mott[145] heated chlorine and methane to yield carbon tetrachloride, which was subsequently heated with more methane to produce lampblack and hydrochloric acid.

Winter[146] burned a mixture of hydrocarbon (vapor or gas) and chlorine in an atmosphere of air to obtain high yields of a very pure carbon and hydrogen chloride. Such a flame consists of a highly luminous interior zone where the chlorine reacts with the hydrocarbons, and an outer oxidation mantle. Gaseous products are separated from the carbon by filtration or electrical precipitation and are washed with water to remove the hydrogen chloride.

The use of chlorine or of hydrogen chloride in the production of carbon black has also been described by Baxter. In one process the hydrocarbons are cracked in the vapor phase in the presence of hydrogen chloride and the resulting products are further treated with chlorine to yield carbon and hydrogen chloride.[147] A chlorinated hydrocarbon can be mixed with untreated hydrocarbon (as for example, carbon tetrachloride with methane) and the mixture subsequently burned.[148] Best results are obtained from such mixtures in which the total chlorine does not exceed the equivalent of hydrogen. The carbon black obtained by such processes can be freed of volatile matter by dispersing it in a gas, such as nitrogen, carbon dioxide or steam, at temperatures of 150° to 900° C.[149] The hydrogen chloride formed can be used again either as such or as a source of chlorine.[150]

In another process,[151] in which hydrogen, acetylene, ethylene and carbon black are the products, methane is treated at temperatures of 950° to 2000° C., at pressures varying from 760 mm. to 25 mm., for periods varying from about 15 seconds to 0.01 second, the required pressure and time of heating required decreasing with rising temperature. The gases formed are continuously withdrawn by suction, a halogen or halogen compound is used as a catalyst, and the ratio of the surface to the volume of the apparatus varies from about 3:1 at 950° to 30:1 at 2000° C. in this method.

PETROLEUM COKE

Petroleum coke is a hard, porous, glistening material, varying in color from slate-gray to black, left as the solid residue from the destructive distillation of petroleum hydrocarbons. In appearance it is similar to the so-called by-product coke made from coal. There are two types of petroleum coke, namely, that produced in coking stills and that formed in cracking operations. The first has been a product of the refining industry for more than a half-century, while the latter has become the principal petroleum coke since the adoption of cracking processes (generally introduced about 1915). Although the quantity of coke formed in coking-still operations has remained fairly constant for many years, the production of cracking-still coke has increased from approximately 200,000 tons in 1921 to nearly 1,100,000 tons in 1928.[152]

In coking stills, crude oils are distilled (usually at atmospheric pressure) until all but about 8 per cent of the volatile constituents of the residue have been driven off. This leaves a layer of coke at the bottom, which may range from 6 inches thick from a Mid-Continent crude to 30 inches from a Mexican crude. The distillation is a batch operation and the still is allowed to cool between runs so that the coke can be broken up and removed.

Cracking stills are usually operated continuously, often under increased pressure. The greater part of the coke formed is deposited in the reaction chamber where a substantial part of the conversion occurs, and its quantity depends upon the character of the charging stock, the temperature, the duration of heating and the pressure.

From a chemical point of view, petroleum coke is to be regarded not as an elementary form of carbon but as a mixture of hydrocarbons containing high percentages of carbon and small percentages of hydrogen.[153] Many hydrocarbons of high melting point comprising the final distillation products of petroleum have been isolated and studied.[154] These are probably intermediates in the pyrolytic decomposition of hydrocarbons to form petroleum coke.[155] Morton[156] obtained from petroleum residues a yellow-green material, crystallizing in needles with a pearly luster. This material, which appeared to be isomeric with anthracene, was called *viridine* and later *thallene*.[157] A compound called *petrocene* was obtained by Tweddle by the redistillation of petroleum residues.[158] It was a green crystalline body having a specific gravity of 1.206 and from it, by distillation, were separated various fractions which were called *carbocene, carbopetrocene,* and *thallene*. Hemilian[159] isolated a hydrocarbon from the highest boiling portions of American petroleum. This compound crystallized from benzene in shining yellow plates melting above 300° C. and was also called petrocene. From Morton's thallene, Smith[160] isolated picene, which had previously been described and obtained in the distillation of brown coal by Burg.[161] Graebe and Walter[162] also isolated picene (see Chapter 2), melting at 330° to 335° C., from the residues of the distillation of Californian petroleum.

[154] A comprehensive review of this field is given by Zaloziecki and Gans, *Chem.-Ztg.*, 1900, 24, 535, 553.

Prunier and David[163] separated a green crystalline body by the redistillation of petroleum residues. This appeared to be a mixture of the fluorescent coloring matter of American petroleum with aromatic hydrocarbons of higher molecular weight than those known at the time. The carbon content of this material varied from 88 to 96 per cent. On treating it with various solvents, Prunier[164] succeeded in isolating a granular crystalline substance soluble in carbon disulphide and in hot chloroform. On evaporating a solution in the latter solvent, a reddish-brown residue, corresponding to the formula $(C_6H_2)_n$, remained. From this residue, other bodies evidently belonging to a new series of hydrocarbons and having equally high carbon contents were isolated. Thus, from its solution in a mixture of alcohol and a little chloroform there were crystallized yellowish slender needles with a pearly luster, melting at 260° C., nearly insoluble in alcohol, ether and warm chloroform, but soluble in petroleum, benzene, and acetic acid. This compound, also corresponding to the formula $(C_6H_2)_n$, formed two picrates having the formulas $C_{24}H_8C_6H_3(NO_2)_3O$ and $C_{24}H_8{\cdot}2C_6H_3(NO_2)_3O$, melting at 185° and 135° C., respectively.

Prunier and Varenne[165] also examined the dark, spongy, brittle residue left in the retorts from the distillation of petroleum, the so-called petroleum coke. A portion of this residue was soluble in carbon disulphide and this extract (containing 93 to 95 per cent carbon) was separated into fractions by means of various solvents. The alcohol-soluble fraction was a pale yellow viscous, oxygenated substance, the ether-soluble fraction was a mixture of orange-colored crystalline hydrocarbons and oxygenated compounds, and the acetic acid-soluble fraction was dark brown and appeared to be the substance to which the fluorescence of petroleum was due. The insoluble portion contained 97.4 to 98.0 per cent carbon.

Sadtler and McCarter[166] separated several hydrocarbons occurring in petrocene. One, melting at 280° C., had the composition of a dimethylanthracene,

$C_{16}H_{14}$, although its properties did not agree with those of any of the then known isomers. The hydrocarbon melting at 178° appeared to be a monomethylanthracene. Both of these substances were undoubtedly contaminated with chrysene, a compound having a higher percentage of carbon and which was extremely difficult to remove. Divers and Nakamura[167] isolated a yellow and a colorless hydrocarbon, both corresponding to the formula $(C_4H_3)_n$ and melting at 280°-285° C., from the last portions of the distillation of a Japanese petroleum. From a Russian mazout, de Boissieu[168] similarly obtained a substance melting at 145°-150° C. The isolation of a hydrocarbon, $C_{24}H_{18}$, called *crackene*, from the pitch of a Saxon lignite tar has been reported by Klaudy and Fink.[169] This compound was believed to be identical with the hydrocarbon $(C_4H_3)_n$ obtained by Divers and Nakamura and with benzerythrene, formed in passing benzene vapor through a red-hot tube.[170]

Zaloziecki and Gans[171] isolated a series of hydrocarbons corresponding to the general formula C_nH_{2n-20} from crude petrocene and to this series they have given the name petrocenes. The melting points of the various hydrocarbons were 140°, 147°, 153°, 155.5°, 168°, 191.5°, 205°, 216°, 221.5°, 228°, 245°-247° and 250.5° C. The compound melting at 250.5° C. had the composition $C_{15}H_{10}$, and yielded a picrate melting at 178° and a bromo-derivative melting at 276° C. When treated with various oxidizing agents no well-defined products were formed but with fuming nitric acid, yellow nitro-derivatives were obtained.

According to Zerbe and Eckert,[171a] the destructive distillation of pitch yields naphthalene, acenaphthene, fluorene, phenanthrene, carbazole, anthracene, methylanthracene, acridine, fluoranthene, naphthofluorene, pyrene, chrysene, and phenylnaphthylcarbazole.

Proximate analyses of cracking- and coking-still cokes, reported by Morrell and Egloff,[172] are given in Table 48:

TABLE 48.—*Proximate Analyses of Cracking- and Coking-Still Cokes.*

Coke Source from Fuel Oils	Moisture	Volatile Matter	Fixed Carbon	Ash	Sulphur	B.T.U. per lb.

Petroleum coke had been a valueless by-product during early years of petroleum refining but has lately been utilized in many diverse ways. The greater part is being used as a fuel,[173] for which purpose it possesses many advantages over powdered coal. Petroleum coke ignites at a lower temperature, the flame propagates faster, the ash content is lower, and it is more easily pulverized.[174] For domestic use, briquettes of petroleum coke are said to be an excellent fuel.[175] Building blocks are made from petroleum coke by mixing the coke with about one-third as much of a binder formed from Portland cement and petroleum coke fines.[175a] Other uses include the manufacture of carbon electrodes,[176] carbon brushes, crucibles, dry cells, and in the form of bricks for electrolytic cells and furnace linings. As it is a reducing agent it has found use in some metallurgical processes and in the reduction of barite to barium sulphide for the manufacture of lithopone. According to Swanson,[177] it is also finding application in the ceramic, cement and abrasives industries as a fuel. Swanson also states that California fruit growers use it for their orchard fires and according to Morrell and Egloff [178] it is now being used for curing "hickory smoked hams."

A number of methods for the production of petroleum coke have been described. Nomi [179] distilled petroleum tar destructively at 500° to 600° C. To obtain coke in the form of irregular scales, Perry [180] heated a thin layer of coal tar, pitch, petroleum, or asphalt on a hot drum. Murray and Ricketts [181] produced coke from oil residues by bringing hot gases into contact with them as they flow in a thin film over the inner surface of a coking chamber. Distillation of heavy hydrocarbon liquids to hard low-volatile cokes was accomplished by Jennison and Faben [182] by passing gases produced by the combustion of carbonaceous fuel into the liquids. Campbell and Herthel [183] and Gullette [184] reduced heavy oils to coke in cylindrical vessels, removing the coke subsequently *en bloc*. An apparatus for the production of petroleum coke was described by Steinschneider,[185] and Tz [186] proposed a method of operating cracking units to produce ash-free petroleum coke. Also, heavy oils may be sprayed into an oven chamber heated from below by horizontal flues. Part of the hot combustion gases from the flues mixed with air is passed in with the oils to attain the temperature necessary for cracking.[186a]

Petroleum coke formed in the cracking of oils can be removed from the residues by filtration. Egloff and Benner [187] obtained purified carbon by washing the residue from the filtration with solvents. The removal of finely divided solid material from distillation gases by washing with water heated to such a temperature that the hydrocarbons ordinarily solid are separated from the gases in the liquid state has also been described.[188]

[187] U. S. Patent 1,535,211, April 28, 1925; assigned to Universal Oil Products Co.; *Chem. Abs.*, 1925, **19**, 1944.

A method of calcining petroleum coke in a rotary kiln was proposed by Walden.[189] In his method of making carbon black, Oberle[190] treated finely disintegrated petroleum carbon with superheated steam. An activated carbon can also be produced[191] by heating petroleum coke in the presence of water and lime to a temperature of 480° to 510° C. or by mixing petroleum coke with sawdust and acid sludge followed by treatment with highly superheated steam.

Steinkopf and Winternitz[192] determined the asphalt content of various oils and the amounts of coke formed from them, both *in vacuo* and at atmospheric pressure. They found that 40 per cent of the hard asphalt present and from 40 to 60 per cent of the soft asphalt were converted into coke. Distillations under reduced pressure yielded less coke than distillations at atmospheric pressure. The best yields of coke from petroleum tars distilled in gas-oven retorts are obtained, according to Allner,[193] at a temperature of 1100° C.

The graphitization of petroleum coke at 2500° C. and the relative catalytic effect of various metals on this process have been studied by Schleifstein.[194] Calcium was found to have the least effect, and boron and chromium had the greatest. All attempts to graphitize petroleum coke in the presence of small proportions of silica, even by heating for 15 hours at 2400° to 2500° C., were complete failures.

PURIFICATION OF HYDROGEN

When hydrogen is generated by the purely thermal decomposition of hydrocarbons, the only impurities usually present in the product are small amounts of hydrocarbons (principally methane) and perhaps some nitrogen. It is extraordinarily difficult to effect complete decomposition of hydrocarbons even at high temperatures, since equilibrium in such pyrolytic processes is approached so slowly. By the pyrolysis of a Polish natural gas at 1700° C., Mantel[195] obtained hydrogen which still contained 0.7 per cent of methane. In many of the processes already outlined, the resulting hydrogen is contaminated by oxides of carbon and small amounts of gaseous hydrocarbons. These impurities are present also in gases produced by the reaction of hydrocarbons with steam at high temperatures (see Chapter 10). The present discussion must necessarily be limited to a brief account of the methods for the removal of only these impurities.

The purity of the hydrogen required for various purposes varies greatly. For certain hydrogenation processes (e.g., coal hydrogenation) a comparatively impure gas is probably quite satisfactory. On the other hand, the hydrogen employed in the catalytic synthesis of ammonia must be free from traces of oxygen, carbon monoxide and water vapor.[196]

Kloepfer[196a] treated the gases (containing hydrogen and methane) with a mixture of 25 to 35 per cent of fused sodium and 70 to 75 per cent of a diluent such as sodium chloride or carbonate. The mixture was heated to a temperature of over 300° C. in order to melt the sodium, but at a low enough temperature to keep the diluent solid.

PURIFICATION BY FRACTIONAL CONDENSATION

One method for obtaining substantially pure hydrogen from mixtures is low-temperature fractionation. This process was developed principally for producing hydrogen from water gas[197] (a mixture of hydrogen and carbon monoxide chiefly) but it has been modified to produce hydrogen from coal gas or coke-oven gas. One method for separating the constituents of coke-oven gas by fractional condensation has been described by Bronn.[198] The gas, previously freed from carbon dioxide by washing successively with water under a pressure of 12 atmospheres and with caustic soda, is subjected to a preliminary cooling to —30° C. to —50° C. by heat interchange with the gases issuing from the system. The gas then enters a separation chamber where it undergoes further cooling by the gases already separated. All the constituents are thus condensed with the exception of hydrogen, nitrogen, and part of the carbon monoxide. The residual gas, still under a pressure of about 10 atmospheres, is then passed through tubes immersed in a bath of liquid nitrogen evaporating under reduced pressure. This effects condensation of the carbon monoxide and almost all the nitrogen, leaving hydrogen of about 98 to 99 per cent purity. If the gases are to be used for the synthesis of ammonia, the residual mixture of hydrogen, nitrogen, and carbon monoxide is washed with a stream of liquid nitrogen to remove the carbon monoxide completely and a mixture of hydrogen and nitrogen results. By treatment with liquid nitrogen under pressure at —180° C. all impurities liquefiable at that temperature (hydrogen sulphide, carbonyl sulphide and the last traces of carbon monoxide) can be removed from hydrogen from water gas.[199]

Bronn and Fischer[200] pretreated the gases at a temperature of —60° C., by washing them at a relatively low pressure with liquid ammonia and an organic solvent for acetylene (acetone). To remove the washing liquid, further cooling to —90° C. may be used.

REMOVAL OF HYDROCARBONS

The high solubility of methane and gaseous hydrocarbons generally in kerosene, gas oil, and other petroleum fractions is well known and it is possible to eliminate hydrocarbons almost completely by scrubbing with such liquids at appropriate pressures. To eliminate hydrocarbons from hydrogen it has been proposed to wash the gas with benzine under pressure at a temperature below —60° C. but above the freezing point of the solvent.[201] According to Gordon and Hughes,[202] methane may be eliminated from mixtures containing hydrogen and hydrocarbons by washing the gas under 250 atmospheres with a high-boiling solvent such as kerosene.

Removal of Carbon Monoxide

A number of methods have been suggested for removing carbon monoxide from mixtures with hydrogen, for example, from water gas or the gas obtained by treating methane with steam or carbon dioxide at high temperatures (see Chapter 10). Bosch and Wild[203] proposed to remove traces of carbon monoxide by passing the gases through sodium hydroxide at high temperatures and pressures. For example, hydrogen containing 1 per cent of carbon monoxide is treated with an 80 per cent solution of sodium hydroxide under 50 atmospheres pressure at 260° C. or with a 25 per cent solution under 200 atmospheres at 240° C.

Carbon monoxide can be absorbed in an ammoniacal solution of a cuprous salt, the method usually used in gas analysis.[204] Huntington[205] proposed to remove carbon monoxide from producer gas by using this absorbent and applying pressure to the gas. The copper solution is regenerated by subjecting the absorbent to a vacuum. Williams[206] and Linde[207] have described similar procedures. Ueno and Kimura[208] treated by-product hydrogen with metallic copper, a cuprous salt and ammonium hydroxide.

The Badische Company[209] used ammoniacal solutions of cuprous chloride under pressures above 100 atmospheres for the absorption but later recommended the use of solutions with excess ammonia[210] or of ammoniacal solutions of cuprous formate or acetate[211] to overcome some of the corrosive action on the iron vessels employed. DeJahn[212] suggested cuprous carbonate. Gordon and Hughes[213] eliminated carbon monoxide and unsaturated hydrocarbons from gas mixtures with an ammoniacal cuprous solution using pressures of 100 to 250 atmospheres.

Frank,[214] in various processes, proposed to conduct previously dried water gas over calcium carbide maintained at a temperature between 300° C. and the melting point of the carbide to separate pure hydrogen. Under these conditions the impurities present in the hydrogen, according to Frank, reacted as indicated below:

$$CO + CaC_2 \longrightarrow CaO + 3C$$
$$CO_2 + 2CaC_2 \longrightarrow 2CaO + 5C$$
$$3CO_2 + 2CaC_2 \longrightarrow 2CaCO_3 + 5C$$
$$O + CaC_2 \longrightarrow CaO + 2C$$
$$2N + CaC_2 \longrightarrow CaN_2C + C$$

Williams[215] proposed to convert carbon monoxide present into methanol, which can then be removed by cooling the gases under pressure. Hydrogen containing 2 to 10 per cent of carbon monoxide is passed under a pressure of 900 atmospheres over a catalyst at 400° C. The catalyst is made by heating zinc carbonate or a mixture of zinc and chromic hydroxides. Methanol is formed from carbon monoxide thus.[216]

$$CO + 2H_2 \longrightarrow CH_3OH$$

REMOVAL OF CARBON DIOXIDE

Removal of carbon dioxide from gas mixtures is relatively easy. Conversion of carbon monoxide to carbon dioxide can be effected with steam in the presence of certain catalysts, according to the reaction:

$$CO + H_2O \rightleftharpoons CO_2 + H_2$$

This reaction is reversible and unless steps are taken to remove the carbon dioxide as it is formed, the resulting gas mixture contains carbon monoxide, carbon dioxide and hydrogen in such proportions that further purification becomes difficult and expensive. Lime and other alkaline contact materials have been suggested for absorbing the carbon dioxide as it is formed.[217] From the work of Engels[218] and others, it appears that the best temperature for this exothermic reaction, which is actively catalyzed by metallic oxides (iron oxide), is 400° to 600° C. Many processes for effecting this conversion have been developed but only a few salient points of these need be noted, since they have been described elsewhere.[219] The reaction temperature is usually 400° to 600° C. and the oxides or iron, cobalt, and nickel dispersed on non-metallic supports have been recommended as catalysts.[220] Other suggested contact materials contain active substances, especially oxygen compounds of copper, chromium, manganese, magnesium, thorium, uranium, beryllium or antimony.[221]

The use of lime water under pressure has also been suggested for washing gases for the removal of carbon dioxide.[222] Gordon and Hughes washed out carbon dioxide, hydrogen sulphide and sulphur compounds with solutions containing ammonia under pressures from 100 to 250 atmospheres.[228] Scrubbing with water under pressures up to 200 atmospheres has also been proposed by Gordon,[224] who subsequently released the pressure to 20 atmospheres to obtain gas richer in hydrogen, leaving gases richer in carbon dioxide in solution. He effected further separation by repeating the process.

Chapter 8

The Carbon Black Industry. Deposition of Carbon from Flames

The industry classifies blacks, which consist of substantially pure carbon, roughly into two divisions, namely (1) carbon black, which is made by impingement of a flame of hydrocarbon gas (usually natural gas) on a surface (generally metallic); and (2) lampblack which is deposited as a soot in the incomplete combustion of a solid or liquid carbonaceous substance in free space (i.e., without impingement).[1] Carbon black is more finely divided than lampblack and for this reason is generally regarded as superior for use in rubber compounding, especially tire tread stock.

This division of blacks into two classes, carbon black and lampblack, depending upon the method of deposition, is by no means a satisfactory one, and a classification based on methods of manufacture would be more explicit and, for the present purpose, more satisfactory. Five such methods have been listed by Chamberlin and Rose:[2]

1. *Incomplete Combustion with Impingement.* A hydrocarbon gas, burning in a limited supply of air, is allowed to impinge on a cool depositing surface. The earliest methods for the manufacture of carbon black from natural gas, such as the so-called channel, disc, roller, and plate processes which will be described in this chapter, were of this type. In point of production these are the most important.

2. *Thermal Decomposition.* A hydrocarbon gas or atomized oil is subjected to thermal decomposition in the absence of air. In this class would fall the "Thermatomic" and other processes described in Chapter 7 for the production of hydrogen and carbon.

3. *Explosion.* A hydrocarbon gas such as acetylene is exploded in a limited supply of air, resulting in decomposition to carbon. Some examples of this class have already been discussed in Chapter 7 and others will be found in Chapter 9.

4. *Incomplete Combustion without Impingement.* A liquid or solid hydrocarbon is burned in a limited supply of air to produce soot which is collected. Lampblack is manufactured in this way. Some processes of this type have been mentioned in Chapter 7.

5. *Destructive Distillation.* Destructive distillation of organic materials produces various kinds of charcoals and cokes (e.g., petroleum coke) which are subsequently pulverized for use.

In Chapter 7 the methods of decomposing hydrocarbons to produce carbon and hydrogen (classes 2, 3, 4, and 5 above) were discussed. In this chapter the principal emphasis will be placed on those procedures in which the hydrocarbons, generally natural gas, are burned with a flame in an insufficient supply of air (class 1 above). From a consideration of the mechanism of this latter process it has been shown that it, too, is a simple decomposition effected by the heat produced by combustion of part of the gas.

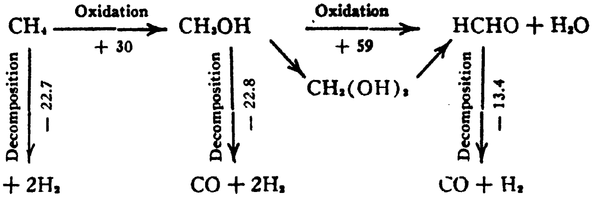
MECHANISM OF CARBON BLACK FORMATION

The production of carbon black by incomplete combustion of gases containing hydrocarbons is not the result of a preferential combustion of the hydrogen of the hydrocarbon but is a direct thermal decomposition. Part of the gas burns producing oxides of carbon, and the heat liberated is sufficient to cause the decomposition of another part of the hydrocarbon gas into carbon and hydrogen. According to Bone and his collaborators[3] the various processes taking place during the combustion of methane can be formulated as follows:



The thermal relationships are indicated in kilogram calories per mole.

Bone[4] and his collaborators, as previously pointed out in Chapter 7, found that the thermal decomposition of methane is a purely surface effect giving rise to a hard graphitic carbon, but the decomposition of ethane, ethylene, and higher gaseous hydrocarbons takes place throughout the entire mass of the gas, leading to a soft form of carbon. It is well known that unsaturated hydrocarbons, such as ethylene and acetylene, can be formed by incomplete combustion of methane or its homologues and consequently (see Chapter 4) there is a possibility that these unsaturated hydrocarbons, and not methane itself, are the generators of the finely divided carbon black.

The function of the metal surface for deposition is twofold.[5] In the first place the liberated carbon is cooled somewhat so that no oxidation changes, or an agglomeration of particles, from too prolonged heating can take place. Secondly, it allows the carbon to be maintained at a high enough temperature for sufficient time to free it from empyreumatic substances. Too cold a metal surface prevents the maximum separation of carbon and too hot a surface causes loss of carbon by agglomeration. The temperature of the depositing surface should normally not exceed 500° C.[6]

When carbon is maintained at high temperatures for any length of time its physical and chemical properties tend to change markedly. An agglomeration of particles takes place followed by the formation of hard gritty lumps somewhat of the nature of graphitic carbon. To obtain the best quality of carbon black it is essential to avoid the prolonged action of heat on the carbon black initially formed.

---

Abs.*, 1915, 9, 2976; Bone and Townend, "Flame and Combustion in Gases," Longmans, Green and Co., New York, 1927, 387, 413, 381. See also Perrott and Thiessen, *Ind. Eng. Chem.*, 1920, 12, 324; and Chapter 37.

[4] *Loc. cit.* *Cf.* Bone and Coward, *J.C.S.*, 1908, 93, 1197.

[5] See Perrott, *U. S. Bur. Mines Bull.* 192, 1922.

[6] This was also confirmed later by the work of Plummer and Keller (*Ind. Eng. Chem.*, 1930, 22, 1209), who found that the optimum temperature of the depositing surfaces for the production of gas black from propane was about 516° C.

Wiegand[7] has studied the characteristics of two types of flames, namely, a round and a flat or "batwing" type in black production, and the factors which influence quality and yields. Comparison of products from the two flames revealed that the carbon black obtained from a round flame was characterized by a grayer color, lower oil absorption and absorptive activity, increased flow characteristics, greater miscibility in rubber but diminished reenforcing effects in rubber composition.

Measurements of the temperature of flames of hydrocarbon gases have been made by Loomis and Perrott[8] and Jones, Lewis, Friauf, and Perrott.[9] The flame temperature is markedly affected by the proportion of combustible gas and air in the mixture, of course. The flame temperature reaches a maximum when the mixture contains combustible gas slightly in excess of that necessary to consume all the oxygen present. The observed maximum temperatures obtained with methane, Pittsburgh natural gas, ethane, butane, isobutane, propane, butylene, propylene and ethylene increased in that order from 1880° to 1975° C. Thus, unsaturated hydrocarbons produce higher maximum flame temperatures than saturated ones. These maximum flame temperatures were found to occur over very narrow ranges of gas-air ratios.

DEPOSITION OF CARBON FROM NATURAL GAS FLAMES

Since natural gas varies widely in composition (see Chapter 1), a difference in the yield and quality of the blacks manufactured from gas from various sources is to be expected. Natural gas frequently contains nitrogen, oxygen, hydrogen sulphide, and water vapor as well as carbon dioxide. Indeed only small proportions of hydrocarbons may be present in the raw gas, in such rare cases as certain wells in Mexico[10] and New Mexico,[11] and in a number of other places[11a] which discharge gas consisting largely of carbon dioxide. The relative proportions of the gaseous paraffin hydrocarbons present in natural gases are of special importance in black manufacture. In general, as will be pointed out later, a gas containing a moderate content of ethane is better than one which is almost entirely methane. West Virginia with its supply of gas high in ethane is a particularly favorable location in this respect.

The yield of carbon black varies from one-half to about two pounds per thousand cubic feet of natural gas.[12] This variation in yield depends mainly upon the process used and the type of product desired and is only slightly affected by the character of the gas. Since 31.82 pounds of carbon and 2000 cubic feet of hydrogen are theoretically obtainable from one thousand cubic feet of methane, the process of producing carbon black must be regarded as wasteful. Many a chemist, calculating the theoretical yield of carbon, feels that he is called upon to make an effort in the cause of conservation, and perhaps, what is more important, to produce carbon black at a lower cost.

That the carbon made by burning artificial gas in a limited supply of air could be used to impart to ink a very glossy and intense black was known to certain manufacturers of printing ink as early as 1864.[13] The first factory [14] for the successful commercial production of carbon black from natural gas was erected in 1872. At this plant at New Cumberland, W. Va., the well was connected to a gas holder, from which the gas passed through pipes to gas jets arranged in the same horizontal plane beneath slabs of soapstone pierced by a number of orifices; these apertures permitted the passage of excess smoke and waste gas. The slabs were covered by a domed roof, provided with a damper for controlling ventilation. Transverse horizontal scrapers below the slabs were supported and travelled in horizontal grooves cut in the lower and opposite sides of the dome. The deposited carbon which was removed by these scrapers then fell into sheet-iron troughs. The depositing surface was kept cool by pans through which water was allowed to circulate continuously. This plant produced a carbon black which was inferior in some properties to the product made from artificial gas. It was subsequently shown that the dome was superfluous, that cast iron was better than soapstone as a depositing surface, and that no beneficial results attended the use of air or water for reducing the temperature of the cooling surfaces.

[13] See Neal and Perrott (*loc. cit.*) and Cabot (*loc. cit.*, also *J.S.C.I.*, 1894, **13**, 128). The history, manufacture, uses and testing of carbon blacks have also been discussed briefly by Cranor and Venuto (*Am. Paint J.*, 1931, **15**, No. 26, 21).

Certain mechanical improvements, particularly in the design and operation of the scraping device, took place at this stage. At Gambier, Ohio,[15] a competing plant was built with a maximum production capacity of 125 pounds per day, which brought about a great reduction in the price of carbon black. A considerable advance was made in 1883 by L. Martin and Co. in a small plant at Foster Mills, Pa. Here five plates, 24 feet in diameter, cast in segments and supported by a central mast rotating with them, were used for deposition of the carbon black. Beneath these plates were fixed stationary burners. In the same year Blood [16] devised the *rotating disc process,* using plates of only 3 feet diameter as depositing surfaces. The advantage of this was that ventilating holes were unnecessary and the plates could be made in one casting. Beneath each plate, which was revolved by a ratchet at the center, was a scraper in the center of a radial hopper, through which the deposit fell into a longitudinal conveyer.

Hallock and Blood [17] proposed and later started the manufacture of carbon black by the so-called *roller process.* A burner with a small hole in the top, giving a rounded flame, was so placed that its flame impinged on a cast-iron roller (hence, the name of the process) rotating at slow speed. Although only a small yield of carbon black, generally of inferior color, was produced, the black possessed certain advantages which have prevented the complete abandonment of the method. The chief uses of this black are in making lithographic and embossing inks and printing ink for half-tone engravings.

These methods of manufacturing carbon black have been almost entirely superseded (except for small quantities of special blacks) by the *channel process,* which was first employed by McNutt [18] in 1892 in a factory erected at Gallagher, Pa. In this process, a system of channel beams turned with the flat side downwards over a horizontal row of stationary burners was given a slow reciprocating motion. The black was scraped off and removed by a spiral conveyer. Channel irons gave a smoother depositing surface than that of unsurfaced cast-iron plates.

The carbon black deposited on channels may be selectively removed and that deposited on the central longitudinal part of the face of the channels collected separately. According to Wiegand,[19] the carbon deposited at different portions of the channels has varying properties.

[18] U. S. Patent 481,240, Aug. 23, 1892.

At about this time an attempt to manufacture carbon black by burning petroleum vapors, or gas enriched by oil vapor, was made by Dysart [20] and Cabot [21] but the use of the product was limited on account of the presence of hard carbon particles. In 1902 a plant was built in West Virginia in which the black obtained by the incomplete combustion of natural gas was collected upon a hollow channel iron, through which a blast of air was blown to cool the depositing surface and to increase the yield of black, but this process has since been abandoned.

From about 1912 onwards attempts were made to produce carbon black by the thermal decomposition of hydrocarbons at high temperatures, already described in Chapter 7. Numerous advances in the incomplete combustion of natural gas have also been made in the meantime.

Martin [22] obtained an increased yield of carbon black by preheating natural gas to 200°-500° C. before burning. Lewis [23] has suggested cooling a portion of the flame separately from the action of the surface by a metal wire or rod passing through it. An enclosure having heat-insulating walls has also been proposed by Lewis [24] to retard the radiation of heat from the plate and flame.

An electrical method of operating a carbon black plant was suggested by Thieme.[25] He connected the positive terminal of a 110-volt direct current electric circuit to a straight iron wire which passed through a luminous gas flame and placed above this wire an iron wire gauze connected to the negative terminal. Lampblack "grows" on the gauze and as soon as the deposit is large enough to come in contact with the straight wire an electric circuit is established. A small magnet connected in series is activated by this circuit, drawing the gauze suddenly sideways and shaking off the lampblack. The circuit is thus broken and the process repeated. A very fine carbon, free from lumps, was obtained. The same result was observed when the terminals were connected to an induction coil so that a short spark passes between them.[26]

Since carbon is an incomplete combustion product of hydrocarbons efforts have been made to secure better yields by stifling the flame in some way, for example, by mixing an inert gas such as nitrogen or carbon dioxide with the hydrocarbon gas.[27]

Lewis [28] has suggested the exposure of the flame and iron depositing surface to ultraviolet light to increase the yield of carbon black in impingement processes.

An apparatus in which an electric current is passed through a flame from which carbon black is being deposited has also been described by Lewis.[29]

Minchin and Downer [30] used two conductors for the deposition of carbon, one of which may be rotated and from which the carbon may be continuously removed and the other, forming the burner, is charged with alternating or direct current and held in the flame of the burning hydrocarbon. In this process the yields are increased by removal of the carbon deposit, by maintaining a uniform temperature, or by cooling.

An apparatus with thermostatic control for producing lampblack by the combustion of materials such as natural gas has been described by Rumbarger.[31]

Wiegand and Venuto [32] agglomerated carbon black, making it less bulky and dusty, by wetting it with water, bringing it into contact with gasoline to displace substantially all the water, and finally evaporating the gasoline. Rubber-compounding ingredients may be added to the black during the process and pellets may be formed.

The spraying of water into the fumes from the partial combustion of natural gas has been recommended by Lewis.[33] The water washes out all the free carbon and condenses the water vapor formed in the combustion. The carbon particles thus deposited are separated from the water.

Yields of carbon black higher than those obtainable by burning a hydrocarbon gas with a continuous flame were produced when the gas was burned in an atmosphere of compressed air. Francis [34] has shown that the yield of high-grade carbon black can be trebled, for example, at 100 pounds pressure. In this work the very great theoretical and practical significance of the upper limit of inflammability of the hydrocarbon gas in luminous flames is clearly demonstrated. At atmospheric pressure the upper limit of inflammability of methane in air is about 14 per cent. Such a mixture contains 18 per cent of oxygen, an amount more than sufficient to combine with all the carbon present in the methane according to the reaction:

$$(1)\ CH_4 + O_2 \longrightarrow CO + H_2 + H_2O$$

The low yields usually obtained are due therefore to the fact that an excess of oxygen for equation (1) is present.

Small amounts of carbon are formed by the side reaction:

$$(2)\ CH_4 + O_2 \longrightarrow C + 2H_2O$$

The relative amounts oxidized according to (1) and (2) are determined by the relative excess of oxygen at some critical point in the flame and by the equilibrium between the products:

$$(3)\ C + H_2O \rightleftharpoons CO + H_2$$

It is obvious, therefore, that to effect an appreciable increase in the yield of carbon, conditions must be so changed as to diminish the excess of oxygen in the flame by raising the upper inflammability limit of the hydrocarbon or by shifting the equilibrium (3) to the left. From the results of Jones,[35] Francis has shown that the addition of inert gases or vapors to stifle the flame as proposed by some is futile.

[33] U. S. Patent 1,801,436, April 21, 1931; assigned to Columbian Carbon Co.; *Chem. Abs.*, 1931, **25**, 3447.

[34] *Ind. Eng. Chem.*, 1931, **23**, 612; U. S. Patent 1,820,657, Aug. 25, 1931; assigned to Magnolia Petroleum Co.; *Brit. Chem. Abs.* **B**, 1932, 490.

The upper limit of inflammability of methane in air increases with increased pressure in the manner illustrated in Table 49.[36]

Table 49.—*Effect of Pressure upon Upper Inflammability Limit of Methane in Air.*

Pressure (atmos.)	1	10	50	125
Per cent methane	13.5	17.0	29.5	45.4

From this it might be expected that by increasing the air pressure around the luminous flame better yields of carbon would be obtained, as Francis proved by direct experiments. By burning gas flames in air under pressures of the order of 12 to 14 atmospheres, he obtained yields of black of 7 to 8.5 per cent (1 pound per 1000 cu. ft. of methane = 3% yield), a decided increase over processes operating at atmospheric pressure. The carbon produced in these experiments was equal in tinting power and apparently identical with the best grades of carbon black on the market.

Francis has also calculated the flame equilibria in a methane-air flame at various pressures and at 437° C. (the temperature giving results most closely in agreement with observed yields) with the results given in Table 50.

Table 50.—*Calculated Yields of Carbon in Equilibrium at 437° C. in a Methane Flame.*

Pressure in Atmos.	Upper Inflammability Limit, CH_4	Yield of Carbon
	Per Cent	
1	13.5	2.93
2	14.1	8.75
5	15.3	16.15
10	17.0	23.1
20	20.5	28.8
30	23.5	32.3
34	24.8	32.7
40	26.5	32.2
60	32.0	30.2
125	45.4	21.6

The calculated percentage yield of carbon increases rapidly with increasing pressure up to about 34 atmospheres and then declines gradually. This decrease is due to the increasing amounts of methane which are prevented from decomposing by the effect of high pressures upon the equilibrium.

With natural gas at its present low price the yield of black is not economically important. It is probably cheaper to burn five times as much gas to produce a given amount of black than to install a process such as the one described above. Nevertheless, as the supplies of gas begin to diminish, methods capable of producing increased yields will take on a new significance, particularly if the black produced by them is of high quality.

Table 51 shows the yield of carbon black produced from natural gas by various processes in different localities, as reported by Neal in 1922.[37]

[37] *U. S. Bur. Mines Bulletin* 192, 1922, 37.

TABLE 51.—*Yield of Carbon Black by Various Processes.*

State	Process	Carbon Black Lbs. per 1000 Cu. Ft. of Gas
Louisiana	Channel	0.78
"	"	0.95
"	"	0.80
"	Large Plate	0.80
West Virginia	" "	1.10
" "	Rotary Disc	0.95
" "	Roller	0.80
" "	Rotary Disc	1.00
" "	Channel	1.12
" "	"	1.30
" "	Rotary Disc	1.40
Oklahoma	Channel	1.20
Wyoming	"	1.40

It is interesting to note, however, that the average yield by the channel process since 1922 has not been as low as indicated in the above table. Thus, the average yield for the entire United States in 1929 (about 90 per cent of which was made by the channel process) was 1.40 pounds per thousand cubic feet of gas and this was increased to 1.43 in 1930 and 1.44 in 1931.[38] The thermatomic process (see Chapter 7), in comparison, is capable of giving consistent yields of 7 pounds of carbon black by the thermal decomposition of one thousand cubic feet of natural gas.[39]

The principal factors influencing the yield and quality of the carbon black produced by the incomplete combustion of natural gas, as given by Chamberlin and Rose,[40] are (1) pressure of gas, (2) rate of burning, (3) nature of the burner tip, (4) composition of gas, (5) position of plate in flame, (6) draft conditions, (7) material of plate, (8) motion of plate, (9) shape of plate, (10) humidity of atmosphere, (11) barometric pressure, (12) temperature of gas, (13) temperature of plate, and (14) uniformity of operating conditions. Dependent upon some or all of the above factors are (a) the height of the flame, and (b) the composition and (c) temperature of the atmosphere in which the flame burns. Burner tips made of lava, a selected steatite, are generally favored in the industry.[41]

Regulation of the air supply is controlled more or less empirically, the color of the smoke issuing from the stack being taken as an index. Admission of too much air will, of course, result in too hot a flame and a large proportion of the carbon will be burned, while too little air will give a flame in which the gas will not be decomposed sufficiently and from which little carbon will deposit. Moreover, in the latter case, the carbon produced is likely to be contaminated by intermediate products of combustion. The rate of rotation of the cooling surfaces also affects the quality rather than the yield of carbon black.

The figures in Table 52, reported by Neal,[42] show the influence of the composition of natural gases from various localities on the yields of carbon black produced by the same process (laboratory test simulating channel process) under identical controlled conditions.

[42] *Loc. cit.*

TABLE 52.—*Yields of Carbon Black from Natural Gas.*

Source	Louisiana	West Virginia	West Virginia	Wyoming
Composition of Gas				
Methane, %	94.12	70.75	65.23	46.45
Ethane, %	3.44	24.14	30.07	43.10
Carbon dioxide, %	0.50	0.28	1.56	0.96
Nitrogen, %	1.94	4.83	3.14	9.49
Net heating value, B.t.u. per cu. ft.	962	1086	1134	1176
Carbon content, lbs. per 1000 cu. ft	33.8	39.9	42.3	44.3
Carbon yield				
Carbon black obtained, lbs. per 1000 cu. ft.	0.80	1.00	1.10	1.40
Recovery of carbon, %	2.4	2.5	2.6	3.1

In the analyses given in the above table the "ethane" figures probably represent not only ethane but also its immediate higher homologues. The yield of carbon black per 1000 cubic feet of gas, and also the percentage recovery of carbon as carbon black, increase with an increase in the proportions of the homologues of methane in the gas.[43]

Recovery of gasoline from natural gas before utilizing it to manufacture carbon black is a large source of revenue and does not reduce the carbon black yield to an appreciable extent.[44]

Sulphur compounds when present in the gas, accumulate on the lava tips, thus decreasing the volume of gas passed through the burner and causing the flame to fork and produce an uneven distribution of carbon over the depositing surface.

DEPOSITION OF CARBON FROM OTHER HYDROCARBON FLAMES

Carbon black was made as early as 1864 from artificial gas. Since that time a wide variety of gases have been thermally decomposed to yield carbon black and hydrogen (see Chapter 7) but the greatest proportion of commercial production of carbon black has been largely restricted to natural gas as a source because of its cheapness. Some consideration, however, has been given to the burning of other gases as well. For example, Berger and Wirth[45] burned acetylene to make acetylene black. Plummer and Keller[46] obtained carbon black from propane and studied the effect of various factors on its production from this gas by the channel system. The product was equal in quality to that made from methane. The conditions of operation using propane or methane show a close agreement and demonstrate the essential identity of the basic flame reactions of the two gases. The partial combustion of diacetylene or a substitution product in a special burner has also been proposed.[47]

Kroch[48] suggested the enriching of natural gas or methane with ethylene or ethane for the production of carbon black. Vaporized oil is added to the gas mixture and this is subsequently cracked and burned in a limited supply of air. The incomplete combustion of heavy oil distillates cracked under low pressure has also been proposed.[49]

---

[43] This is supported by the later work of Plummer and Keller (*Ind. Eng. Chem.*, 1930, **22**, 1209) on the production of carbon black from propane by what was essentially the channel process. Yields of about 3 lbs. per 1000 cu. ft. of gas were obtained while the results suggested an identity of basic flame reactions with those occurring in normal carbon black production from methane.

[44] See Chapter 1. An absorption process for recovering gasoline from the residual gases of compression plants has been described by Dykema and Neal, *U. S. Bur. Mines Tech. Paper* **232**, 1920.

[48] U. S. Patent 1,815,851, July 21, 1931; *Chem. Abs.*, 1931, **25**, 5523. Numerous methods for the enrichment of gases with petroleum oils or for the burning of petroleum oils have been previously suggested. See, for example, Neff and Fales, U. S. Patent 160,786, Mar. 16, 1875; Cabot, U. S. Patent 491,923, Feb. 14, 1893; Dysart, U. S. Patent 343,446, June 8, 1886; Lampblack, Ltd., British Patent 17,223, 1912; Maiser, German Patent 203,711, 1909; Siemens and Co., German Patent 291,727, 1914; Wegelin, U. S. Patent 807,646, Dec. 19, 1905; Neal and Perrott, *U. S. Bur. Mines Bull.* **192**, 1922.

A mixture of 15 to 70 per cent hydrogen and a hydrocarbon gas such as methane has been used by Lewis[50] for the production of carbon black by incomplete combustion in which the flame is allowed to impinge on a collecting surface. Such a mixture is obtained when natural gas, stripped of its heavier constituents, is passed through a tube heated to between 600° and 900° C.[51] At this temperature hydrogen, methane and cyclic hydrocarbons but no free carbon are formed. The cyclic hydrocarbons are removed by condensation before the gas is burned to carbon black. The cyclic hydrocarbons may be retained in the gas by insufficient cooling.[52] In another method by Lewis[52a] for the production of carbon black, a hydrocarbon gas is oxidized with insufficient air in a special burner designed to project alternate layers of hydrocarbon and air, the spacing and rate of flow of which are adjusted to minimize turbulence.

The incomplete combustion of oils to obtain carbon black has also been suggested. Egloff,[53] for example, discharges residual oil from one still into a second still where air is injected into the oil while it is still at a temperature above its flashpoint. An apparatus for burning oil mixtures has also been described by Lewis.[54] The production of lampblack by burning liquid hydrocarbons while flowing in a thin film over an inclined surface of which the temperature is adjusted by a cooling liquid has been suggested by Morrell and Mekler.[54a]

Strout and Lyder[55] admitted air at a number of points to a petroleum oil to effect incomplete combustion. The quantity of air is controlled in such a manner that no additional heating is required. The gaseous waste products, after being freed from carbon, may be used to control the temperature by mixing them with the air.[55a] Beaver[56] burned contiguous flowing streams of hydrocarbons and insufficient air in a heated enclosed chamber to produce carbon black.

Begrov[57] has described an apparatus in which petroleum hydrocarbons may be converted to lampblack. After passing a hydraulic seal, light petroleum fractions are admitted into the upper end of a heated coil consisting of a number of banks, and the vapor which is discharged through perforations at the bottom is burned.

Methods for the direct formation of printer's ink have been described by Miller.[58] In one process 1 part of hydrocarbon oil is decomposed into carbon and gases by incomplete combustion with 5 to 9 parts by weight of air at a temperature between 1093° and 1426° C. The gases are removed rapidly from the zone of reaction at a minimum constant velocity of 500 feet per minute and cooled while at the same speed. The carbon particles are separated from the products of combustion by causing the gases to impinge against a film or sheet of an oily ink vehicle. This oil vehicle is continuously withdrawn, mixed with a fresh quantity of the same vehicle, cooled and again spread into a film for further removal of carbon from the gases. Unabsorbed oil-laden carbon particles can be removed, after reducing the velocity of the gases, by electrical precipitation. Miller and Masson[59] deposited carbon in a liquid base using an apparatus consisting of a number of rotating perforated discs dipping into the liquid. The products of combustion on passing through one disc impinge upon the wetted surface of the next one. Miller[60] produced carbon black by thermally decomposing a portion of the hydrocarbon oil in an inner zone heated by combustion of another portion of the oil in an outer zone. The hydrocarbon oil is continuously supplied to the decomposition zone while the air necessary for the partial combustion enters only the outer zone.

Physical and Chemical Properties of Carbon Black

Ultimate analyses show that carbon blacks contain substances other than carbon.[61] Appreciable proportions of volatile and small proportions of mineral matter are usually present. In good-grade blacks, however, the mineral (ash) content is extremely small. The analyses in Table 53 show the compositions of various carbon blacks used for ink making and of two made by the thermal decomposition of methane. The so-called "long" blacks are used for making the fluid "long" inks (i.e., inks which can be drawn out into a string between the fingers), whereas the "short" blacks produce inks of a buttery consistency which

do not flow rapidly—the so-called "short" inks.[62] In the former, fluidity is of importance since it permits the ink to be distributed rapidly in thin films over printing surfaces without rupture of these films.

It will be noticed that blacks which are classified as long blacks contain more volatile matter, oxygen, and moisture than the short blacks. When the analytical results are compared it is found that carbon made by decomposing methane at high temperatures (No. 1) is nearly pure carbon. When decomposition is effected at a lower temperature (No. 2) considerable amounts of napththalene and other volatile substances are present. Lampblacks, on the other hand, unless well calcined, invariably contain high proportions of volatile matter (up to 20 per cent). Table 54 shows the results of analyses of blacks from various sources of lampblack and carbon from cracking of natural gas.

In appearance carbon black is a black velvety powder with an extremely low apparent specific gravity. It owes its remarkable properties to its extreme state of division. The particles of which this powder is composed are very small, being below the resolving power of the microscope in size. Recent work on the particle size of these blacks using ultraviolet microscopic and x-ray spectrographic methods has demonstrated the impossibility of exact measurements. Discussion of the particle size of carbon blacks has been given by Goodwin and Park[63] and by the Wegelin A.-G.[64] The former employed micro-photographic methods using a milled-in mixture of black and clean pale crêpe rubber dispersed in xylene. The particle size of various blacks was found to increase in the order: Super Spectra (a channel-process black for use in varnishes), Micronex (also a channel-process black for use with rubber), Goodwin (a black made by incomplete combustion of natural gas at high temperature) and Charlton (an oil black), and Thermatomic (a black made by thermal decomposition of natural gas). The particles of Super Spectra were so fine that they could be photographed only with difficulty. Both Goodwin and Charlton blacks have particles of about equal size. Upon x-ray examination these blacks all gave the same type of pattern and breadth of line coinciding approximately with the order of particle size given above.[65] The indications are that the particles of carbon black do not exceed 0.1 to 0.2 micron (0.0001 to 0.0002 millimeter) in size, on the average, but in view of the tendency of blacks to agglomerate too much reliance cannot be placed in this figure.

Carbon black particles agglomerate when dispersed in various liquid media.[66] Under the microscope freshly prepared mixtures of thin lithographic varnish with short and long carbon blacks appear quite similar. After a few minutes, however, the particles of the short black begin to agglomerate into groups of 20 or 30 particles loosely bound together, and after an hour clusters of over a hundred have formed. These agglomerates may be resolved mechanically into their components, but they again coalesce rapidly. On the other hand, the long carbon black particles show very little tendency to agglomerate. Perrott (*loc. cit.*) suggested that the absorbed impurities (volatile matter), which are present to a larger extent in long blacks, prevent this agglomeration of particles. This conclusion is supported by the fact that treatment of long blacks with steam at

[62] *Short flow* and *long flow* are inadequate classifications, the distinction being transitional, according to Kearsley and Roberts (*Ind. Eng. Chem., Anal. Ed.*, 1931, **3**, 310). A quantitative method of determining the fluidity, which is described more fully in the section on the uses of carbon black, has been proposed by them.

500° C. produces blacks which exhibit this tendency to agglomerate. The dispersibility of gas black has also been studied by Allen and Schoenfeld.[66a]

Because of their very fine state of division, carbon blacks always occlude large amounts of gases, mainly oxygen, nitrogen and oxides of carbon. At ordinary temperatures the composition of the gas pumped off from samples of carbon black is practically that of air, the volume of the gas being approximately equal to the volume of the voids and capillaries in the carbon. Hulett and Cude[67] obtained the results in Table 55 on pumping away the gases from various types of carbon blacks at ordinary temperatures by a Töpler pump:

At higher temperatures, and particularly at 445° C., a much larger volume of gas is usually evolved, consisting chiefly of oxides of carbon. The composition and volume of gas pumped away at 445° C. are given in Table 56.

TABLE 56.—*Gas from Carbon Blacks at 445° C.*

The oxygen evolved as oxides of carbon and also as free oxygen would account for only a portion of the total oxygen present, the rest probably being held in non-volatile compounds.[68]

The rates of evolution of gas from carbon blacks at various temperatures and pressures have been recorded by Johnson.[69]

The crystalline structure of carbon black particles has been investigated by a number of workers.[70] While the consensus of opinion is that both carbon black and charcoal are essentially graphitic in nature, the evidence is not altogether convincing and authorities are not in complete agreement.

Chaney, Ray, and St. Johns, *Ind. Eng. Chem.*, 1923, **15**, 1244. Oswald (*Chimie et Industrie*, 1930, **24**, 280; *Brit. Chem. Abs.* **B**, 1930, 974) has identified two varieties of amorphous carbon—a brown, truly amorphous carbon and a gray pseudo-amorphous graphitic form.

Hofmann and Groll[71] obtained a carbon having the crystalline structure of graphite by dropping benzine (boiling point 60° to 70° C.) from a capillary through a vertical quartz tube heated to 950° C. According to Plummer,[72] the theory that appears to be in greatest accord with the general properties of the so-called amorphous carbons is that they are not modifications of elemental carbon (plus certain adsorbed impurities) but that they consist of unsaturated hydrocarbons of very high molecular weight and highly deficient in hydrogen; i.e., carbon complexes in which the fields of force between the carbon atoms are unbalanced by an occasional stray hydrogen atom, thus preventing crystallization (graphitization) and producing a general state of unsaturation and hence high surface activity. This general view has also been supported by Lowry,[73] who found that the hydrogen content of charcoals heated to about 1000° C. was still 0.48 per cent and at 1300° C., about 0.1 per cent, while the coefficients of surface activity (i.e., cc. of CO_2 adsorbed per cu. mm. total pore volume) did not decrease appreciably until above 1000° C.

Of the physical characteristics of carbon blacks, adsorptive capacity is of great importance, especially as a factor in its use in rubber compositions. According to Goodwin and Park[74] this property is the one which exerts the most profound influence upon the character of a rubber mix, an influence which is more particularly shown by a tendency to retard the rate of cure of the mix and by a surface-tension effect between the pigment and the medium. This view is supported by the later work of Carson and Sebrell[75] and Wiegand and Snyder.[76] Twiss and Murphy[77] thought the differences in the rate of cure of various rubber mixes containing carbon black were attributable to the adsorption of more or less of the natural accelerator of the rubber by the filler. Other workers, however, have been unable to find any correlation between adsorptive capacity of the black and its properties in rubber mixes. Spear and Moore,[78] for example, observed no general relationship between stiffening effect or rate of cure of carbon blacks in rubber and the adsorption of either acidic or basic dyes from water or benzene. Beaver and Keller[79] also failed to note any correlation between acetone extract, iodine adsorption, or oil adsorption of carbon blacks and the rate of cure or aging of the resulting rubber compositions. They did find, however, that oxygen adsorbed on the black had a retarding effect in the mix.

The adsorptive capacity of carbon blacks has been measured by using solutions of substances such as benzoic acid,[80] iodine,[81] dyes[82] (e.g., methylene blue), oils,[83] hexamethylenetetramine,[84] alkalies,[85] diphenylguanidine,[86] and acetic acid.[87]

For example, Carson and Sebrell,[88] in carrying out the determination with iodine, shook 0.25 gram of the black with 50 cc. of standard iodine-potassium iodide solution and then, after centrifuging to settle the black, determined the excess iodine with standard sodium thiosulphate solution. Goodwin and Park[89] used a solution of iodine in carbon tetrachloride and allowed the black to settle by standing, with, if necessary, the addition of diatomaceous earth.

Wiegand and Snyder[90] determined the adsorptive capacity of carbon black by using diphenylguanidine. One gram of the black is shaken for 2 hours with 50 cc. of an alcoholic solution of diphenylguanidine (2 grams per liter of alcohol), the black is removed by filtration, and the quantity of diphenylguanidine remaining is determined by titration of 25 cc. of the filtered alcohol with standard hydrochloric acid, using a mixture of bromophenol blue and methyl red as the indicator.

Very intimately connected with the subject of adsorptive capacity is that of the adhesion tension of blacks. This subject has been discussed by Bartell and Smith,[91] who measured the adhesive values of several commercial blacks against water and benzene. The method of Bartell and Osterhof,[92] which they used, depends upon the measurement of the pressure set up when a given liquid displaces air, or a second liquid, from a membrane of finely divided solid material packed in a displacement cell. It was shown that different commercial blacks possess different adhesive tensions against water and benzene and that heat treatment of the blacks tends to reduce this tension. According to Bartell and Miller[93] a direct relationship exists between adhesive tension and adsorption when a given solid is used with different liquids.

The heats of combustion of carbon blacks and various other forms of elemental carbon have been determined by Roth and Doepke[94] and Plummer.[95] Perhaps the most remarkable result of the work of the latter is the observation that the heats of combustion of carbon blacks which have been degassed at 1000° C. are higher than that of graphite and, in fact, are the highest of any known form of carbon. Roth and Doepke and Plummer found that prolonged heating at 1000° C., or higher, results in a gradual lowering of the heat of combustion, a result which is to be ascribed to slow crystallization (graphitization). Plummer's results for various carbons subjected to different treatments are given in Table 57.

TABLE 57.—*Heats of Combustion of Carbon Blacks.*

340 calories per gram higher than that obtained for graphite. Roth and Doepke found a difference of 292 calories per gram between graphite and their "most highly" amorphous carbon and attributed this difference to the existence of a distinct modification of amorphous carbon. A somewhat different interpretation, involving the existence of highly unsaturated high molecular weight hydrocarbons, substantiated by this work, has been previously discussed.

The color and tinting power of carbon blacks has been correlated with their other physical properties by Perrott,[96] Johnson[97] and Hock.[98] Goodwin and Park[99] determined the tinting strength of various blacks by mixing 0.05 gm. of the black with a known weight of zinc oxide in boiled linseed oil until a standard color intensity (Micronex carbon black with 2 grams zinc oxide) was attained. Their results, which are given in Table 58, were considered to indicate the particle size, except possibly in the case of Super Spectra, which was probably so finely divided as to have passed the optimum obscuring power.

TABLE 58.—*Tinting Strength of Various Blacks.*

Carbon Black	Oil Used Drops	Zinc Oxide Grams	Relative Tinting Strength
Charlton	60	1.275	0.63
Micronex	60	2.000	1.00
Super Spectra	60	1.778	0.88
Thermatomic	20	0.263	0.13
Goodwin	40	0.996	0.50

In this discussion the properties of only a few carbon blacks have been tabulated. Comparisons have also been reported for other varieties, using the methods and procedures already outlined. Thus, Dawson and Hartshorne[100] analyzed acetylene black and lampblack. The properties of the Thermatomic[101] carbon blacks, Thermax and P-33, have been evaluated and Plummer[102] has reported the characteristics of carbon blacks made from propane.

The properties of a carbon black called "Gastex," made by the partial combustion of natural gas, have also been reported.[103] Table 59 gives a comparison of the properties of "Gastex" with those of other carbon blacks:

TABLE 59.—*Comparison of Properties of "Gastex" and Other Carbon Blacks.*

USES OF CARBON BLACK

The carbon black industry is dependent on the availability of large supplies of cheap natural gas and cannot survive in localities where higher-priced uses for the gas have been found. This fact explains why the industry has had to migrate from West Virginia into Louisiana (about 1920) and later (1928) into the Panhandle (Texas) district. Until the utilization of gas from the prolific fields of Louisiana, about 75 per cent of the world's supply of black was manufactured in West Virginia.[104] In 1929 the industry was largely located in Texas and Louisiana, while less than 3 per cent of the total output of carbon black represented the combined production of West Virginia, Wyoming, Oklahoma, Montana, and Kentucky.[105]

Of the natural gas used in 1929, about 14 per cent of the total was consumed in the manufacture of carbon black. About 87 per cent of the gas which was burned for carbon black was stripped for gasoline. The carbon black industry and the natural-gas gasoline industry are obviously complementary to some extent.[106]

Carbon black is used extensively in the manufacture of the following products, the percentages indicating the proportion of the total domestic deliveries in 1931: (1) rubber (83%), (2) ink (9%), (3) pigments and enamels (4%), and (4) other products (4%), such as shoe and stove polishes, gramophone records, carbon papers, typewriter ribbons, bookbinder's board, hard rubber, artificial stone, crayons and insulating materials. The statistics in Table 60 indicate the total production of carbon black in the United States in 1928, 1929, 1930 and 1931, and the distribution in its various applications.

TABLE 60.—*Production of Carbon Black in the United States.*

Production (in pounds)	1928	1929	1930	1931
By Channel process	220,532,000	327,552,000	350,254,000	255,322,000
By other processes (including disc, Lewis, roller, "special" and Thermatomic)	28,258,000	38,890,000	29,688,000	25,585,000
Total pounds	248,790,000	366,442,000	379,942,000	280,907,000
Domestic Sales (in pounds)				
To rubber companies	140,938,000	138,474,000	128,572,000	134,315,000
To ink companies	27,223,000	27,350,000	19,220,000	15,184,000
To paint companies	20,040,000	17,257,000	11,922,000	6,760,000
For miscellaneous purposes	14,475,000	8,896,000	7,565,000	5,453,000
Exported	77,903,000	91,829,000	84,260,000	96,714,000
Total pounds	280,579,000	283,806,000	251,539,000	258,426,000

Carbon black, which was first added to rubber as a pigment about 1915, has almost completely displaced zinc oxide as a filler in the rubber industry. It is used in all kinds of rubber materials but its use in tires is by far the most important application.[107] Carbon black is used in automobile tread stocks in quantities up to 45 per cent of the rubber or 27 to 28 per cent of the final composition. As illustrating the effect and importance of carbon black in such a use it may be stated that 2 pounds of black suitably incorporated in a small tire will increase the life of the tire from 5,000 miles to about 20,000 miles. The increased durability of tires containing carbon black has saved motorists millions of dollars. From a theoretical viewpoint, carbon black is an ideal filler because of its finely divided condition and low specific gravity. It appears to protect the rubber substance from the effects of light and may retard oxidation.[108]

[106] Hopkins and Backus, *loc. cit.* See also Carney, *J. Inst. Pet. Tech.*, 1930, **16**, 118; *Chem. Abs.*, 1930, **24**, 5134.

[107] The use of carbon black in rubber insulating compounds has been discussed by Wiegand and Boggs (*Ind. Eng. Chem.*, 1930, **22**, 822). Mixtures of rubber, carbon black, and a tasteless mineral oil have been suggested as substitutes for chicle in chewing gum (Zimmerli and Semon, U. S. Patent 1,829,029, Oct. 27, 1931; assigned to B. F. Goodrich Co.). For effects of carbon in rubber see also Spear and Moore, *Ind. Eng. Chem.*, 1926, **18**, 418.

Lampblack has been used since the invention of the printing press as a pigment in printer's ink but since 1864 it has been almost entirely replaced by carbon black. The latter is now absolutely indispensable in the manufacture of most inks, the various blacks being carefully chosen for the purpose according to their particular characteristics. As pointed out previously, certain blacks produce the so-called short inks (i.e., inks of buttery consistency which do not flow rapidly), which are especially suitable for lithographic and offset work, in slow-speed presses and for most half-tones. For these purposes lampblack is unsuitable. Other types of black produce the so-called long inks which, on account of their more rapid flow and opacity, are employed in fast-running presses. Attention should be directed to the fact, however, that the largest application of carbon blacks in ink involving the highest speed presses, namely news ink, actually makes use of short channel blacks. This is because news inks are not made with a varnish base as are book inks, but are manufactured with ordinary non-drying and free-flowing petroleum oils.

Kearsley and Roberts [109] have suggested a method for determining the effect of carbon black on the fluidity of printing ink. Their procedure consists in mixing carbon black with ten times its weight of a standard lithographic varnish, and allowing ten drops of the mixture to drop onto a horizontal glass plate maintained at a definite temperature. After allowing the mixture to come to the temperature of the plate the latter is then set at an angle of 30° and the rate of flow of the carbon black mixture is determined.

Carbon black is finding increasing application as a pigment in various paints and enamels. It has a higher tinting strength than any other black and is generally acknowledged to be superior for varnishes and enamels. The application of carbon black as a coloring agent in paints, varnishes, and lacquers accounted for deliveries of 17,257,000 pounds in 1929, or 9 per cent of the total domestic sales.[110] Both long and short carbon blacks ordinarily possess a reddish-brown undertone which can be partially corrected by the use of blue dyes ("toners") but which renders these blacks unsatisfactory for certain inks. In certain gray tints, however, lampblack may be superior to carbon black on account of its bluish-gray tone.

For other purposes, carbon black is employed because of its high coloring power, highly dispersed condition, and low cost. Although it may be possible to substitute lampblack for carbon black for some purposes (for example, in the manufacture of phonograph records, medical hard rubber, and certain types of inks and paints), the question of such substitution is largely a matter of economics. The relative development of the natural-gas industry in the United States and of the coal-tar industry in Europe create an economic urge toward the use of carbon black in the United States and of lampblack in Europe, whenever possible.[111]

[109] *Ind. Eng. Chem., Anal. Ed.*, 1931, 3, 310.

[110] This dropped to 6,760,000 pounds in 1931 or 4 per cent of the total domestic sales.

[111] A discussion of the manufacturing difficulties encountered by the German carbon black industry is given by Hadert, *Paint and Varnish Production Mgr.*, 1932, 7, No. 5, 32; *Chem. Abs.*, 1932, 26, 3336.

TESTING OF CARBON BLACKS

Neal and Perrott,[112] in their account of the carbon black industry, described a number of physical and chemical tests which may be used for determining the characteristics of a sample of carbon black and its probable value for various purposes. Some of these tests and results have already been discussed in a previous section of this chapter. Of the chemical tests the determinations of moisture and ash are most useful.

The moisture content, which is determined by heating a sample of black for 1 hour at 105° C. in a constant-temperature oven in circulating dry air, should not be more than 4 or 5 per cent for use in printing inks or rubber. Table 61 gives the figures found by Goodwin and Park[113] for the moisture content of various typical blacks, in per cent of the original weight. After the moisture content was determined the dried blacks were placed in an ice box for 24 hours. The gain in weight is given in the second column as per cent (on the basis of the dry sample) fluctuation of moisture.

TABLE 61.—*Moisture Content of Blacks.*

Black	Moisture	Fluctuation of Moisture
	——Per Cent——	
Charlton	2.90	3.5
Micronex	2.80	3.8
Super Spectra	5.70	6.7
Thermatomic	0.06	0.3
Goodwin	0.08	0.5

The differences in moisture content appear to depend upon the adsorptive capacity of the black.

The ash content, determined by ignition to about 750° C. (a cherry-red heat), should not exceed about 0.2 per cent for most purposes. Higher results indicate adulteration with mineral black or charcoal.

The determination of the organic material extractable by boiling acetone has been shown by Goodwin and Park[114] to be a matter of some difficulty owing to the tenacity with which the material is retained by the black. The fact that extracted material is readsorbed when placed in contact with the original material is further evidence that the extraction process involves an adsorption equilibrium. The method of extraction preferred by them consists in extracting 1 to 2 grams of the air-dried black together with 3 or 4 grams of diatomaceous earth with boiling acetone for 5 days in an Underwriter's apparatus. The extract is then dried overnight at 56° C. and weighed. The extraction of the five blacks investigated gave the results shown in Table 62.

TABLE 62.—*Acetone Extraction of Blacks.*

Black	Extract Per Cent
Charlton	3.70
Micronex	0.23
Super Spectra	0.27
Thermatomic	1.64
Goodwin	1.44

[113] *Ind. Eng. Chem.*, 1928, **20**, 621.
[114] *Loc. cit.*

In the opinion of Goodwin and Park, the amount of extractable matter bears no relation to the quality of the black, and since it is practically impossible to determine the total extractable matter, they attach little importance to this test.

Other useful characteristics are the real and apparent densities of the sample. Details of the methods for this determination are also given by Goodwin and Park and they report the values for typical blacks shown in Table 63.

TABLE 63.—*Specific Gravities and Apparent Densities of Blacks.*

Black	True Specific Gravity	Apparent Density, Gm./cc.
Charlton	1.66	0.15
Charlton (extracted with acetone)	1.71	—
Micronex	1.79	0.26
Super Spectra	1.89	0.11
Thermatomic	1.84	0.65
Goodwin	1.82	0.12

The other tests, such as the estimation of tinting power, color, grit, and hiding power or spreading rate, are empirical but are valuable in deciding the possible application of the black.

Butcher[115] and Cranor and Venuto[116] have also outlined methods of testing carbon black.

Chapter 9

Transformation of Hydrocarbons by Electrical and Other Special Forms of Energy

Electric treatment of hydrocarbons may be roughly classified according to whether the energy is supplied by an electric arc (sparking), or by a silent electric discharge, often called *voltolization.* Treatment with alpha particles and similar forms of energy could be included in the latter category. Although in many cases a similar ultimate result may be attained by either method, yet there are important differences. Chemically, the major difference is that the electric arc involves cracking of the molecule into smaller fragments or radicals, whereas the silent electric discharge generally induces polymerization into larger molecules, often accompanied by dehydrogenation. In the silent electrical discharge a relatively thin film of material is subjected to a high voltage between highly charged surfaces, but no actual sparking takes place. In the high-tension arc, sparking occurs across a permanent gap and in the low-tension arc, the electrode is first raised to a high temperature heating the surrounding gas so that it becomes a good conductor and allows the passage of a current in the form of an arc at comparatively low voltages.

THE ELECTRIC ARC

The action of the electric arc, or of electric sparks, on various types of hydrocarbons produces extensive decomposition accompanied by the formation of numerous products of which carbon, hydrogen and acetylene are usually important. Because of the intense heating effect of the arc, its action is, in many respects, comparable to the changes taking place when hydrocarbons are subjected to severe pyrolytic operations.[1]

Of the early investigators, Dalton[2] and Henry[3] reported that methane was decomposed into carbon and hydrogen by electric sparks.[4] When "pit gas," freed from carbon dioxide, was subjected to such treatment for 30 hours, Bischof[5] observed that only one-third of the methane had decomposed and the carbon formed possessed a strong odor of turpentine. He therefore attributed the complete decomposition observed by Dalton to the presence of moisture in the gas. Buff and Hofmann,[6] Franchimont,[7] Lepsius[8] and Plesniewicz[9] have also resolved methane into carbon and hydrogen by treatment with electrical sparks.

This action of the electric arc on mixtures of hydrocarbon gases is the basis of a number of processes for making hydrogen.[10]

Berthelot[11] was probably the first to show that considerable quantities of acetylene were produced when methane, and other hydrocarbons, were subjected to the electric arc. Ludeking[12] pointed out that methane yields hydrogen and carbon when both the electrodes are metallic or one is metallic and the other carbon, but that acetylene is formed when both electrodes are made of carbon.

The formation of acetylene from other hydrocarbons by the action of an electric arc, either high or low tension, is of practical importance and is associated from a scientific point of view with the increasing thermodynamic stability of that substance at high temperatures.

Bone and Jerdan[13] showed that the direct combination of carbon and hydrogen to yield acetylene could take place in the electric arc, so that the reaction

$$C_2H_2 \rightleftharpoons 2C + H_2$$

was reversible under such conditions. These same investigators, by the prolonged action of an electric arc on methane, admixed with a small quantity of nitrogen, obtained a gas having the composition, hydrogen cyanide 0.8 per cent, hydrogen 85.6 per cent, acetylene 9.8 per cent, methane 2.5 per cent and nitrogen 1.3 per cent. Of interest in this connection is the production of saturated hydrocarbons, which Carter and Campbell[14] stated takes place under the influence of a low-voltage carbon arc discharge in water. At the same time a small proportion of a sparingly soluble acid of high melting point is obtained.

The effect of a high-tension arc on substantially pure methane has been investigated by Stanley and Nash.[15] The main products of the reaction were acetylene, carbon and liquid and solid hydrocarbons, though ethylene and a small proportion of diacetylene ($HC{\equiv}CC{\equiv}CH$) were also found in the reaction gas. In addition to gaseous products and carbon, small quantities of light oil, chloroform-soluble tar, and resinous substances were produced. The light oil was highly unsaturated, had a pronounced tendency to resinify, and formed explosive silver derivatives, thus indicating that acetylene homologues were present. Both naphthalene and acenaphthylene were isolated from the tar. The occurrence of diacetylene among the reaction products is interesting since this hydrocarbon has been obtained in other operations, particularly in the electropyrolysis of alcohol[16] and the treatment of fuel oil with a low-tension arc.[17]

Frolich, White, Uhrmacher and Tufts[18] recorded some experiments on the decomposition of methane in an ordinary carbon arc. Acetylene was the main product under all conditions, although some ethylene (up to 1.5 per cent in the resulting gas) was formed also. Carbon deposition was largely suppressed and the acetylene yield markedly increased by diluting the methane with hydrogen. With methane and hydrogen in the ratio of 1:2 as much as 51 per cent of the methane was converted into acetylene by one passage through the arc. It was suggested by Frolich and his collaborators that the added hydrogen reduces carbon deposition because of its influence on the high-temperature equilibrium.

$$C_2H_2 \rightleftharpoons 2C + H_2$$

since this reaction has been shown to be reversible under the experimental conditions. When ethane was passed through the arc, acetylene and ethylene were obtained in approximately equal volumes, while, as in the case of methane, low gas velocities resulted chiefly in the cracking of the hydrocarbons to carbon and hydrogen.

When employing voltages ranging from 8,000 to 47,000, methane, ethane, and ethylene are transformed to acetylene and hydrogen, together with other substances.[19] In the case of methane, acetylene and hydrogen, in the ratio of 1 : 5, were formed; ethane yielded a variety of materials including hydrogen, acetylene, methane and ethylene; and ethylene gave hydrogen and acetylene, in the ratio of about 2:1, and some methane. Heptane vapors at 4 to 12 mm. pressure, however, when subjected to a low-tension discharge (300 to 600 volts between nickel electrodes) yielded hydrogen and a condensation product.[20] The latter had practically no vapor pressure, was slightly soluble in organic solvents, and slowly absorbed oxygen from the air.

A study of the decomposition of liquid and solid hydrocarbons in the (low tension) electric arc was made by Contardi.[21] This was an endeavor to obtain an insight into the mechanism of cracking, and various hydrocarbons such as benzene, hexane, amylene, toluene, pseudocumene, petrolatum, paraffin, naphthalene, and others were subjected to an explosive electrical discharge under different conditions. Hydrocarbons of widely different types yielded gaseous products of a similar character indicating that the chief reactions were the same in all cases. The analytical data showed that the first two of these, namely,

$$\begin{array}{ll} & 2CH_4 \longrightarrow C_2H_2 + 3H_2 \\ \text{and} & C_2H_6 \longrightarrow C_2H_2 + 2H_2 \end{array}$$

proceeded with enormous velocities in the hot zone. The secondary reactions. viz.,

$$\begin{array}{ll} & C_2H_2 \longrightarrow 2C + H_2 \\ & C + 2H_2 \longrightarrow CH_4 \\ \text{and} & 2C + 3H_2 \longrightarrow C_2H_6 \end{array}$$

which occur at the same time, are completed in the cold zone (1200° C.) at the expense of the carbon formed. Methane and ethane, on account of the latter reactions, do not again reach the hot zone and so appear in the final products. Hydrocarbons very rich in hydrogen, e.g., hexane, yielded a gas which at first contained about 18 per cent of acetylene. On continued action of the electrical discharge the liquid became heavily charged with carbon and the acetylene content of the gas increased to 33-34 per cent.

In some experiments on the production of acetylene in the electric arc by methods applicable on an industrial scale, Contardi directed his attention to the use of coal tar and anthracene oil. In an arc between iron or carbon electrodes at 50 volts and 40 amperes, anthracene oil yielded a gas containing 22 per cent acetylene, 50 per cent methane, 23 per cent hydrogen and 5 per cent nitrogen. Graphitic carbon was deposited at the same time. The temperature of the oil in which the electrodes were immersed did not exceed 120° to 130° C. A coal-tar oil gave a gas having the composition 24 per cent acetylene, 45.4 per cent methane and 0.8 per cent nitrogen. Carbon deposition amounted to about 10 per cent of the oil.

[20] Christen, *Anales inst. investigaciones cient. tecnol.*, 1932, 1, 71; *Chem. Abs.*, 1933, **27**, 4743.

[21] *Atti congresso naz. chim. ind.*, 1924, 358; *Chem. Abs.*, 1925, **19**, 1941. *Giorn. chim. ind.*, 1925, 7, 195; *Chem. Abs.*, 1926, **20**, 3230.

Attention has been given to the possibility of making acetylene by the action of the electric arc on mixtures of saturated gaseous hydrocarbons, such as natural gas, coal gas or coke-oven gas, which contain a large proportion of methane. The results of such an investigation have been reported by Fischer and Peters.[22] The main portion of their work was concerned with the action of high-tension sparks on coke-oven gas containing principally methane and hydrogen (23.4 per cent methane and 52.3 per cent hydrogen) at pressures of 2 to 60 mm. At reduced pressures the number of ions is enormously increased, a fact which leads to the supposition that under such conditions the efficiency of the discharge would be greatly enhanced. A reaction chamber of glass having iron electrodes 20 to 120 mm. apart was used. The main gaseous products of the reaction were observed to be acetylene and hydrogen, together with some ethane. The best conditions for obtaining acetylene were a pressure of 40 to 50 mm., a distance between electrodes of 40 mm., and high gas rates. Under such conditions the reaction gas contained 8.5 per cent of acetylene and the energy consumed per cubic meter was 31 kilowatt-hours, with an efficiency of 15 per cent. Experiments with pure methane were rendered difficult owing to the formation of carbon in the reaction chamber.

Further work on the conversion of methane in coke-oven gas into acetylene under reduced pressures has been recorded by Peters and Pranschke.[23] They were able to reduce the energy required from 31 to 12 kilowatt-hours per cubic meter of acetylene, thereby increasing the electrical efficiency from 15 to 38 per cent. They also found that best results were obtained with gas mixtures containing 50 per cent or less of methane. When the methane content was higher than 50 per cent the acetylene formed apparently took part in other reactions.

Peters and Wagner[24] determined the minimum energy consumption for the production of acetylene or ethylene to be 13 and 53 kilowatt hours per cubic meter, respectively. Under these conditions using a gas mixture containing 2 moles of methane and 1 mole of hydrogen, the exit gases contained 4.2 per cent acetylene and 0.8 per cent ethylene. It was apparently impossible to suppress acetylene and increase ethylene production except at very low pressures and high energy consumptions. Generally the proportion of acetylene in exit gases increased with the energy supplied, the maximum concentration being 30 per cent. In the case of ethylene the maximum concentration did not exceed 3 per cent.

The effect of reducing the pressure during the electrical decomposition of natural gas (92.5 per cent methane, 3.5 per cent hydrogen, and 3.9 per cent nitrogen) was investigated by Jones.[25] Platinum wire electrodes were employed, and the pressure was varied from 100 to 700 mm. of mercury. Analysis of the gaseous products appeared to indicate that the main reaction was the decomposition of methane into carbon and hydrogen, although high percentages of olefinic and acetylenic hydrocarbons were formed. The highest yield of acetylene was obtained at about one-half an atmosphere pressure. At still lower pressures, 1 to 11 mm., Montagne[26] believed the principal reaction to be the decomposition of methane into acetylene and hydrogen (proceeding to the extent of about 75 per cent) but this is complicated by subsequent decomposition and condensation of the acetylene. Even at low temperatures (e.g., liquid air) as much as 10 per cent of the methane is transformed into saturated or ethylenic hydrocarbons.

Although acetylene is the principal hydrocarbon resulting from the action of the electric arc on hydrocarbons under most conditions, nevertheless other substances may be obtained in considerable yields. Ethylene appears to be an important product, and diacetylene, as previously noted, has been observed in some instances. Curme[27] has developed a process for decomposing fuel oil in a regulated alternating current arc into a gas consisting of about 50 per cent hydrogen, 12.5 per cent ethylene, 25 per cent acetylene and 5 per cent of other hydrocarbons among which diacetylene is an important constituent. The relatively high proportion of ethylene in comparison with the acetylene yield is noteworthy. According to Brooks,[28] Curme was able to prepare diacetylene in considerable quantities and to determine accurately the properties of this hydrocarbon.

Diacetylene was prepared by Müller and Bänninger[29] by the decomposition of benzene in a low-tension arc. Some higher acetylenes were formed at the same time, as well as phenylacetylene, $C_6H_6C{\equiv}CH$. The gaseous reaction products contained 86 to 87 per cent hydrogen and 9 to 10 per cent of acetylene. To explain these results, it was assumed that a primary dissociation of the benzene into the radicals C_6H_5— and $CH{\equiv}C$— was followed by a secondary recombination of such radicals.

Under certain conditions, moreover, it appears that higher olefins and diolefins may be produced from lower members of the olefin series (particularly ethylene) when the latter are exposed to a high-temperature arc at a higher rate of flow than that required for making acetylene.[30]

The gaseous products of the decomposition of mineral oils by a high-tension arc have been examined by Evers.[31] Some of these were found to contain as high as 50.3 per cent hydrogen and 45 per cent unsaturated hydrocarbons, and only about 1 per cent methane. The unsaturated hydrocarbons were separated as bromides, and from the less volatile fractions a bromide, $C_6H_4Br_8$, was isolated which melted at 82.8° C. In addition some liquid materials as well as a dark brown solid of variable composition (90 to 94 per cent carbon, 3 per cent hydrogen, and 4 to 7 per cent oxygen) were obtained.

Mention has been made of the effect of diluting methane with hydrogen before subjecting it to the electric arc. Other gases may be employed, the effect created varying with the individual gas used. The substitution of ammonia, for example, for hydrogen results in the formation of hydrogen cyanide, a 1:1 mixture of methane and ammonia giving a 70 per cent yield.[32] With higher proportions of ammonia, as in a 3:7 methane-ammonia mixture, a good yield of crystalline ammonium cyanide is secured. The addition of ammonia prevents the accumu-

lation of hydrocarbons, since both tars and hydrocarbons react with it to form hydrogen cyanide.

When mixed with carbon dioxide, or steam, and subjected to a high voltage (5,000 to 6,000) arc, methane is converted to carbon monoxide.[33]

$$CH_4 + CO_2 \longrightarrow 2CO + 2H_2$$
$$CH_4 + H_2O \longrightarrow CO + 3H_2$$

No deposition of carbon takes place. With a lower voltage a part of the methane is converted into acetylene. By varying the voltage and the initial gas mixture the composition of the reaction gas can be altered over a wide range.

Many of the industrial processes dealing with the decomposition of hydrocarbons, either liquid or gaseous, are concerned with the production of acetylene and hydrogen. Methane is especially mentioned as appropriate raw material in several of these, probably because of its abundance and cheapness. This is of particular interest in connection with the better utilization of natural gas, of which methane forms the preponderating constituent, since the resulting acetylene may be employed in welding operations or in the preparation of numerous organic substances. A survey of such processes for making acetylene and hydrogen indicates that they differ principally in constructional details of the equipment. In one procedure the gases, containing both methane and hydrogen, are passed through the arc at atmospheric pressure, the deposition of carbon being prevented by the hydrogen.[34]

Gross[35] described a method in which coal gas, containing both methane and ethylene, is subjected to an electric discharge by passage through a reaction chamber consisting of the annular space between a conical rotor and a conical stator. On both of these, projections (serving as the electrodes) are arranged spirally. The reaction gas is subsequently compressed to remove tarry constituents, and is then bubbled through an absorbent (e.g., acetone) to separate acetylene. In this manner one ton of coal gas is said to yield 280 cubic meters of acetylene.

In another form of apparatus, designed by Gmelin and Eisenhut,[36] the hydrocarbon gases or vapors are passed through an arc formed between a central insulated electrode grounded at the end and a surrounding tubular counter-electrode. The length of arc can be adjusted by a movable insulating mantle of quartz or steatite between the electrodes so as to obtain optimum production of acetylene. Mixtures of hydrogen and methane can be used as the initial materials, but the yield of actylene is materially increased by the presence of other hydrocarbons, either saturated or unsaturated (e.g., ethane, ethylene or oil gas). Thus, mixtures containing (1) 30 per cent methane and 70 per cent hydrogen, (2) 15 per cent methane and 85 per cent ethylene, and (3) 30 per cent ethylene and 70 per cent hydrogen, when conducted through the apparatus give 70 to 80 liters, 100 to 110 liters, and 110 to 140 liters, respectively, of acetylene per kilowatt-hour of electrical energy expended. In a related process[37] acetylene in the exit gas is converted to benzene, which is removed by adsorption with activated charcoal, and the residual gases are treated with oxygen or steam forming a mixture of carbon monoxide and hydrogen.

Saturated hydrocarbon gases at any desired pressure may be subjected to several arcs, the lengths of which are varied according to the changing composition of the gas.[38] As an illustration, the gases obtained during the hydrogenation of coal are passed through successive arcs 200, 280, and 350 mm. in length, the acetylene formed being removed after each arc. In other processes for the production of acetylene and hydrogen it has been suggested that the hydrocarbon gas be passed over the arc under reduced pressure,[38a] or conducted over it at such a rate that the ratio of the amount of gas in cubic meters per hour to the kilowatt power of the arc is between 0.6 and 1.6.[38b]

Several procedures described by Hull [39] involve the rapid passage of the hydrocarbon gases through the reaction zone in such a manner as to impart whirling motion or turbulence to the gases. One way in which this is obtained is by feeding a number of streams of gas to the arc, one of which distends the arc while the others impinge on one another. Another method is the creation of an electric discharge between a hollow conducting tube, having its mouth shaped convergently in the direction of gas flow, and an opposing rod electrode. The gas traveling along the hollow tube at a high velocity distends the electric discharge into the tube. When using high tension arcs the electrodes are made of, or tipped with, carbon. With low tension arcs Hull suggested electrodes consisting of tungsten, molybdenum, osmium, tantalum, or the carbides of these metals.[40]

Mercier [41] has proposed the following manner of operation, particularly for the conversion of liquid hydrocarbons into gases. An arc is struck while the two electrodes are in contact, and these are then separated from one another to the maximum extent consistent with the stability of the arc; or the oil is led through the center of hollow stationary electrodes, which have conical ends, thus allowing the spreading of the arc which jumps between them and the opposite insulated movable electrodes. The gases formed are simultaneously cooled by the oil pumped through the electrodes (a condition favoring the production of acetylene) and removed from the system by a vacuum pump. Yields of acetylene as high as 16 per cent are said to be obtained when the hydrocarbon oil, in a fine state of division, is conducted through a furnace so arranged that an electric arc formed therein has an energy consumption of 2 kilowatts per second per cubic centimeter of space.[42] Other methods for the conversion of liquid petroleum hydrocarbons to acetylene consist in spraying a stream of the oil alone[43] or mixed with hydrogen[44] into an electric arc.

Coals, tars, resinous or asphaltic materials yield acetylene on treatment in an electric discharge according to a process which provides that the decrease from no-load to working tension is not more than 30 per cent.[45] If nitrogen is present, hydrogen cyanide is formed.

A number of procedures have been developed for the separation of acetylene from gaseous mixtures of hydrocarbons. These are discussed in Chapter 4. Two methods, however, may be mentioned. One of these, the mechanical separation of ethylene, is described by Eisenhut.[46] The gas mixture around the arc is composed of a zone rich in and a zone poor in acetylene. The former is withdrawn separately from the apparatus.

Another method of separation involves the use of selective organic solvents, particularly ketones.[47] The reaction gases are washed, best under pressure, and acetylene and other unsaturated hydrocarbons subsequently recovered by distillation of the solvent. In the aliphatic series, methyl ethyl ketone, methyl propyl ketone, diethyl ketone and diacetone can be employed and of the cyclic ketones, acetophenone, cyclohexanone, and methylcyclohexanones are recommended.

When hydrocarbon gases are exposed to the electric arc for a shorter period of time (i.e., at a higher rate of flow) than that required for acetylene formation the result is the production of higher olefins and diolefins.[48] For example, when ethylene (97 per cent purity) was passed at the rate of 40 liters per hour through an electric arc between carbon electrodes having a consumption of about 200 watts, the resulting gas mixture had the following composition: unsaturated hydrocarbons, 64.2 per cent; hydrogen, 29.9 per cent; methane, 3.6 per cent; and nitrogen, 2.3 per cent. Analysis indicated the unsaturated hydrocarbons to consist of the following:

	Per Cent by Weight
Unaltered ethylene	69.5
Propylene	15.0
Butylene	1.8
Butadiene	5.7
Acetylene	8.0

If the above operation be carried out continuously at a higher rate of flow and with continuous removal of the butadiene after formation, then higher yields of this diolefin are obtainable, accompanied by a reduction in the output of acetylene. Greater conversion of the olefin into butadiene may also be effected by prolonging the circulation of the gases, or by applying more electric energy.

Butadiene, together with other olefins and diolefins, is obtained when petroleum or mineral oils in the vaporized or finely divided state are conducted through electrical discharges at 700° to 800° C. Electrodes of copper or its alloys, chromium-nickel alloys, iron, or carbon seem to be particularly applicable for this type of conversion.[49] Olefins and diolefins may be produced also by leading the vapors of mineral oils through a bed of bituminous fuel heated electrically.[50] In this instance the fuel is placed in a fire-brick shaft having electrodes in the walls.

It has been pointed out that the efficiency of utilization of electrical energy in the manufacture of acetylene from hydrocarbons in the electric arc is increased by raising the current density of at least one of the electrodes to the point at which loss of material can be detected.[51] It has also been suggested that the electrical energy fed to the arc be such that the Balmer series of H lines be distinctly visible, at least to the Hδ line. It is recommended that the consumption of electrical energy be 2 kilowatts per cc. of space filled by the arc.[52]

As previously mentioned, acetylene is formed when a gaseous mixture of methane and hydrogen is subjected to the action of the electric arc. By adding nitrogen to the mixture both acetylene and hydrogen cyanide are produced simultaneously.[53] The mixture of hydrogen, nitrogen and methane is circulated through the arc until the concentration of the hydrogen cyanide is about 1 per cent and that of the acetylene about 2 to 3 per cent by volume. The reaction gases are then scrubbed with caustic soda solution and passed through active charcoal to remove the hydrogen cyanide and acetylene, respectively. The residual gases are returned to the system for recirculation.

Other methods for obtaining hydrogen cyanide by the reaction of hydrocarbons with nitrogen are discussed in Chapter 10.

Hydrogen, derived from the reaction between carbon monoxide and steam, is mixed with hydrocarbon gases and the mixture is washed with alkali carbonate solutions both before and after being subjected to the arc. The first alkali wash removes any carbon dioxide, and the second alkali wash absorbs hydrogen cyanide and any hydrogen sulphide formed in the arc. The bicarbonate solution resulting from the first wash may be decomposed by heating, and the carbon dioxide used to liberate hydrogen cyanide and sulphide from the second solution.[54]

Replacing the hydrogen in gaseous mixtures by steam or carbon dioxide results in the formation of acetylene, hydrogen, and carbon monoxide from these oxygen-containing gases and the hydrocarbons.[55] By mixing the initial gases in the correct proportions and then removing the acetylene after the reaction, a residual gas mixture of hydrogen and carbon monoxide applicable for the synthesis of methanol is made.

The action of electric arcs, sparks, or silent discharge on hydrocarbons, particularly olefins, in the presence of hydrogen and carbon monoxide has been suggested as a method for the synthesis of higher molecular compounds.[56] For example, butylene may be obtained from propylene in this manner, the reaction being represented by

$$C_3H_6 + 2H_2 + CO \longrightarrow C_4H_8 + H_2O$$

Similarly benzene is converted to its homologues. It is recommended that the electrodes be made of or tipped with iron, aluminum, copper, nickel, ferro-nickel, sodium or potassium or alloys of these metals and that the reaction be carried out at temperatures up to 500° C. and pressures as high as 30 atmospheres. Another procedure for the synthesis of higher hydrocarbons consists in subjecting gaseous mixtures of hydrogen, carbon monoxide, and saturated or unsaturated hydrocarbons to high frequency electrical oscillations together with or followed by a heat treatment at temperatures above 900° C.[57]

THE SILENT DISCHARGE

Although in certain severe cases the silent electric discharge has been found to split the C—C linkage in the molecule, the usual observed effect is dehydrogenation followed by polymerization through the nascent unsaturated valences. In this respect the effect of the silent discharge is similar to that obtained at high temperatures, as has been shown by Davis[58] to occur with acetone and benzol. The difference between the two cases, however, is that most of the material treated at high temperature is converted to lower molecular weight products, whereas in the silent electric discharge high yields of condensation and polymerization products are obtained.

Berthelot[59] reported that methane, ethane and ethylene when subjected to the silent discharge yielded a little acetylene, free hydrogen, and resinous condensation products. Ethane produced some free ethylene and a polymerized liquid of the approximate formula, $(C_{10}H_{16})_6$. Benzene was found to unite with two atoms of hydrogen and then form a polymer of dihydrobenzene, (C_6H_8), and oil of turpentine after absorbing 2.5 atoms of hydrogen also polymerized.

Later Berthelot[60] observed that methane, under the influence of the silent discharge, lost one-half of its hydrogen and yielded a solid hydrocarbon of the composition $C_{10}H_{18}$. In the presence of nitrogen, methane yielded a solid basic substance, C_2H_3N. This, Berthelot considered, as possibly a polymerized acetylenylamine. Similar results were obtained with ethane, a solid compound, $C_{10}H_{18}$, again being formed, though it was not identical with the substance derived from methane. Ethane in the presence of nitrogen was transformed into a solid basic material, $C_{16}H_{32}N_4$. Olefins, such as ethylene and propylene, gave solid hydrocarbons, and in the presence of nitrogen were changed to basic nitrogenous compounds. In each instance the products were of much higher molecular weight than the initial hydrocarbon, indicating that after first losing hydrogen the molecule must have undergone considerable polymerization and condensation. Acetylene, under similar conditions, produced no hydrogen, but was changed first to a liquid and then to a solid. The latter was rapidly oxidized on exposure to air, and decomposed violently when heated. In the presence of nitrogen, the solid compound, $C_{18}H_{16}N_2$, was formed.

Losanitsch and Jovitschitsch[61] noted that ethylene was polymerized by the silent discharge (3.5 amperes at 70 volts) to a thick yellow liquid boiling above 200° C. This substance absorbed oxygen readily, forming a viscous oil[62] having a composition corresponding to $(C_{12}H_{22}O)_2$. Similarly equal volumes of ethylene and methane condensed to a clear, yellow, viscous liquid. The latter also absorbed oxygen, yielding the compound $C_{22}H_{42}O_4$. Under the same conditions ethylene and hydrogen sulphide quickly condensed to form the compound $(C_2H_4S)_6$, a yellowish-red liquid with a mercaptan-like odor. The reactions yielding the latter are probably

$$C_2H_4 + H_2S \longrightarrow CH_3CH_2SH$$
$$6CH_3CH_2SH \longrightarrow (C_2H_4S)_6 + 6H_2$$

Some evidence for such reactions was that ethyl mercaptan when subjected to the silent discharge also gave the compound $(C_2H_4S)_6$.

When using slightly more energy (3 amperes and 100 volts) Jovitschitsch[63] obtained from ethylene the substance, $C_{30}H_{54}$, which he considered to be a cyclic compound. When treated with nitric acid at 50° to 60° C., two nitro compounds were obtained. The first, having the formula $C_7H_{11}NO_2$, was soluble in hot alcohol, and the second, $C_6H_9NO_2$, was insoluble. Thénard[64] observed that ethylene was similarly condensed to a liquid possessing a strong odor and soluble in ether but insoluble in water. Methyl ether decomposed yielding 1 volume of methane and 2 volumes of hydrogen, a strong acid. and a resinous substance. The latter was soluble in alcohol but insoluble in ether.

Somewhat more information concerning the polymerization products from ethylene has been furnished by Collie.[65] The liquid obtained after this olefin was treated for a considerable length of time with the silent discharge was fractionated. A small amount distilled below 100° C., and the greater part came over between 100° C. and 250° C. (more than half below 175° C.). A large proportion (about 40 per cent) of resinous material was left as a residue. Analysis of the fractions indicated they were mixtures of C_nH_{2n} hydrocarbons containing from 6 to 15 carbon atoms. From the lowest boiling fraction there was also isolated a substance which, from its chemical reactions, appeared to be a polymerized compound. Collie suggested that under the influence of the silent discharge ethylene yields hydrocarbons having the approximate formula, $C_{10}H_{20}$. These lose hydrogen and polymerize to substances having properties somewhat like india-rubber and compositions very close to $(C_5H_8)_n$.

Stratta and Vernazza[66] also noted that a variety of products were obtained from ethylene. They believed these to be the result of (a) direct condensation of two or more molecules of ethylene, (b) transformation to double and triple bonded condensation products, or (c) the formation of ethane or methane and its homologues from interaction of liberated hydrogen and unsaturated hydrocarbons. These investigators also found that the condensation of ethylene is proportional to the concentration of ethylene and the net rate of acetylene formation from ethylene decreases rapidly with the time as a result both of diminution in concentration of ethylene and secondary condensation of acetylene. According to Szukiewicz,[67] acetylene is converted by the action of the silent discharge into ethylene, erythrene, diacetylene, butane, hexane and other hydrocarbons.

Volmar and Hirtz[68] studied the hydrogenation of ethylene in an electric discharge. A slow stream of ethylene and hydrogen (at 20 mm.) was submitted to the silent discharge. The reaction velocity and yield of saturated hydrocarbons increased proportionately to the concentration of hydrogen. Methane was the chief product, but some ethane and propane were also obtained. It was suggested that the primary reaction is the breaking up of ethylene into CH_2 radicals which then react with hydrogen to give methane, or with a second molecule of ethylene to yield (after hydrogenation) propane, or decompose to carbon and hydrogen. Acetylene under similar conditions gave acetylene hydrocarbons containing as high as 10 carbon atoms and saturated hydrocarbons up to 8 carbon atoms. Volmar and Hirtz concluded that activated hydrogen was probably the hydrogenating agent.

When working under conditions which allowed the products of the reaction to be withdrawn rapidly, Mignonac and Vanier de Saint-Aunay[69] observed that the primary product was 1-butene and from this 1-hexene was formed. They represented the reactions by:

$$(1)\quad CH_2{=}CH_2 + H\cdot CH{=}CH_2 \longrightarrow CH_3CH_2CH{=}CH_2$$

$$(2)\quad CH_3CH_2CH{=}CH_2 + H\cdot CH{=}CH_2 \longrightarrow CH_3CH_2CH_2CH_2CH{=}CH_2$$

Low temperatures (—80° C.) favored the yield of 1-butene and raising the temperature increased the yield of 1-hexene. This formation of higher molecular weight hydrocarbons from ethylene had been observed also by Demjanov and Prianischnikov,[70] who obtained a yellow mobile oil (d^{20}_{4} 0.8360 and average molecular weight of 215) when using a silent discharge of 12,000 to 13,000 volts. The oil was thought to contain unsaturated hydrocarbons consisting of hexene (C_6H_{12}) and higher.

The latter investigators also reported that isobutylene gave a product having an average molecular weight of 140 and d^{20}_{4} 0.822, which was composed of principally C_8H_{16} and $C_{12}H_{24}$ hydrocarbons. Later Prianischnikov[71] investigated some of the fractions from distillation of the product. Two fractions in particular, one boiling between 32° and 52° C. and the other between 75° and 85° C., were mixtures containing about 20 to 30 per cent of unsaturated hydrocarbons (C_nH_{2n}) and 70 to 80 per cent of saturated hydrocarbons (C_nH_{2n+2}). 2,2-Dimethylbutane and 2,3-dimethyl-2-butene were probably present in the first fraction, and 2,2- and 2,4-dimethylpentanes and 2,2,3-trimethylbutane, in the second. Fractions of higher boiling points were richer in unsaturated hydrocarbons and also contained some naphthenes. The reactions produced by the silent electric discharge are apparently not only simple polymerization, but are also accompanied by a redistribution of the hydrogen atoms. These effects are somewhat similar to those observed by Ipatiev when ethylene was subjected to high temperatures and pressures (see Chapter 2). Prianischnikov also noted that the properties of the products were influenced by the duration of the discharge (time factor).

Amylene vapor, when mixed with hydrogen, and treated with an electrical discharge in an ozonizer, was converted (about 85 per cent) into liquid products in which saturated hydrocarbons of the C_5H_{12} type (or isomers) predominated.[72] Some unsaturated hydrocarbons, such as isopropylacetylene, were also found. The gaseous products were acetylene, allylene, vinylacetylene and diacetylene. Alone or mixed with nitrogen, no saturated hydrocarbons were produced from amylene. The hydrogen appeared to act not only as a hydrogenating but also as a dehydrogenating agent, uniting with a hydrogen atom of the unsaturated hydrocarbon and bringing about unions of the resulting hydrocarbon residues. This would explain the formation of compounds with double the number of carbon atoms. Amylene also appears to undergo a number of other transformations, including bond transpositions, rearrangements, cyclicization, molecular cleavage, formation of simple and multiple bonds, and polymerization. From their data Meneghini and Sorgato were unable to differentiate between these various transformations. In addition, under the experimental conditions, reactions take place which lead to an increase in internal energy, and therefore the endothermic character of the triple bond brings about the formation of large quantities of acetylenic hydrocarbons. When a discharge tube producing a corona effect was employed the proportion of amylene transformed was much less, though the changes were more deep-seated and separation of free carbon occurred.

According to Koenig,[73] the action of the silent electric discharge on gases is a very complicated process in which primary and secondary reactions take place almost simultaneously. The layer of gas close to the wall of the reaction tube remains practically undisturbed, even with rapid flow, and is not carried away, thus remaining exposed to the further action of the discharge. This difficulty can be overcome, at least in part, by washing the wall of the reaction tube with a liquid. In this way, for example, much better yields of formaldehyde[74] may be obtained in the electrical treatment of water gas, if the reaction chamber is flushed every few minutes with water which washes the formaldehyde from the walls, thus avoiding its destruction by the electric discharge. Similarly with the aid of a reflux condenser attached to the discharge tube, it is possible to obtain the primary products of the electrical decomposition of hydrocarbons (e.g., diphenyl from benzene and diphenylmethane from toluene) without subjecting these materials to further change. Koenig also pointed out that the primary effect of the electron bombardment of the gas molecules consists (1) in loosening, or in tearing off, electrons (ionization), (2) in disintegrating the disrupted molecules provided they do not emit their surplus energy as light waves, and (3) in condensing the unsaturated residues, which are the result of this disturbance, to yield new substances.

Acetylene is readily polymerized when subjected to the silent discharge. Thus Losanitsch[75] converted acetylene into a viscous or solid mass which could be separated with alcohol or ether into soluble and insoluble portions. The soluble portion was a viscous, fragrant oil, which rapidly absorbed oxygen, yielding the substance $(3C_2H_2.C_2H_4.O)_5$. The insoluble solid portion, of the formula $C_{48}H_{46}$, had a very disagreeable odor and absorbed oxygen to give the compound $C_{48}H_{40}O_8$. Both of these oxygen derivatives yielded an emanation which liberated iodine from a potassium iodide solution and through aluminum or gold leaf affected a photographic plate. Losanitsch did not consider this emanation to be radioactive in character, but rather to result from the absorbed oxygen present in a labile state. He also noted that acetylene, in the presence of the silent discharge, could be condensed with other substances such as hydrogen, methane, ethylene, hydrogen sulphide, carbon monoxide, and sulphur dioxide.

Jovitschitsch[76] considered the product obtained from acetylene to have the formula $C_{30}H_{26}$. From this he was able to prepare di-, tri-, and tetrabromides ($C_{30}H_{26}Br_2$, $C_{30}H_{25}Br_3$, and $C_{30}H_{24}Br_4$, respectively) and with fuming nitric acid apparently a trinitro compound, $C_{30}H_{25}O_{30}N_3$.

Later, Kaufmann[77] pointed out that the reaction product is a liquid when the apparatus is kept cold, but a mixture of a solid and a liquid when warm. On dissolving the liquid product in ethyl ether and warming (to about 60° C.) the same solid can be obtained. The liquid is a brown viscous oil of unpleasant odor, having the composition $(C_2H_2)_n$. On distilling, a small portion comes over at 70° C. (10 mm. pressure), the remainder carbonizing or changing to a plastic mass which ultimately becomes solid. The solid is a pale yellow, odorless powder, insoluble in all solvents. Both the liquid and solid compounds can be oxidized, the former much more readily than the latter. On oxidation they both yield benzoic, isophthalic, and terephthalic acids. The liquid product forms a pale yellow precipitate with alcoholic silver nitrate, indicating the presence of the $—C{\equiv}CH$ grouping. The action of the oxygen derivatives of both the solid and liquid substances on a photographic plate was observed, but it was further noted that this action occurred only while the absorption of oxygen was actually taking place.

[75] *Ber.*, 1907, 40, 4656.

[76] *Monatsh.*, 1908, 29, 5.

[77] *Ann.*, 1918, 417, 34; *Chem. Abs.*, 1919, 13, 1825.

Mignonac and Vanier de Saint-Aunay,[78] in experiments at low temperatures (—60° C.), observed that acetylene was polymerized mainly to a trimer, boiling at —10° C. and having a $d^{19.5}_{4}$ 0.752. This trimer slowly underwent further polymerization. When oxidized with permanganate it yielded formic, oxalic, propionic, and succinic acids. It also formed an ozonide which on hydrolysis gave formaldehyde. Reactions of the trimer with alcoholic silver nitrate or cuprous chloride indicated that it might be a mixture of (1) dipropargyl, (2) 3-methyl-1,4-pentadiine $(CH{\equiv}CCH(CH_3)C{\equiv}CH)$ and (3) divinylacetylene $(CH_2{=}CHC{\equiv}CCH{=}CH_2)$.

The paraffin hydrocarbons also disintegrate under the action of the silent discharge. Thus, Lind and Glockler[79] found that when ethane was submitted to a silent discharge of 12,000 volts in a Siemens ozonizer tube, through which the gas was continuously circulated by means of an all-glass magnetic pump, most of the ethane was decomposed in 3 hours, yielding a gas consisting mainly of hydrogen, methane, and propane with smaller amounts of higher homologues. At the same time as much as 45 to 55 per cent of the ethane was converted into a viscous, reddish-yellow oil of density 0.862 and n^{20} 1.490. This oil had the composition: carbon 85.48 per cent and hydrogen 13.09 per cent. Its apparent molecular weight in benzene was 467, and it readily formed substitution products with bromine. The action of the silent discharge was very similar to that produced by α-particles from radon. Later, Lind and Glockler[80] showed that it was possible to regulate the molecular weight of the liquid product obtained by the action of the silent discharge, corona, and high-frequency discharge on ethane by removing the liquid reaction products from the walls of the reactor. By thus controlling the time that the initial products, either gaseous or liquid, were allowed to remain under the influence of the discharge, the average molecular weights of the liquids formed could be regulated between 105 and 467. The secondary action took place the more the higher the molecular weight of the substances produced by further condensation.

These same investigators[81] extended their work to include methane, propane, butane and ethylene. The results with these hydrocarbons were analogous to those obtained with ethane; that is, the action of the silent discharge resulted in the formation of hydrogen, higher homologues of the paraffin series, and a liquid condensate corresponding in formula to C_nH_{2n}. Comparing these data with those obtained with α-rays led to the conclusion that "for all of the hydrocarbons studied the condensations by alpha rays and in electrical discharge have many points in common, which lead to the belief that they both are brought about by the same agency." Comparison of the product of the M/N values (ratio of the number of reacting molecules to the number of ion pairs) and the molar ionization also indicates a similarity between the α-ray and electrical condensations.[82]

[81] Lind and Glockler, *J.A.C.S.*, 1930, **52**, 4450. For the production of acetylene from methane by silent discharges, see Institut für physikalische Grundlagen der Medizin, British Patent 362,869, 1930, addition to British Patent 340,862; *Chem. Abs.*, 1933, **27**, 1421.

Vanier de Saint-Aunay[83] found that by rapid circulation and intense cooling of the gases, the action of high-frequency and low-frequency discharges can be made to yield definite compounds. Methane may be dehydrogenated to give hydrogen and free radicals, the latter condensing for the most part to ethane. Ethane, by dehydrogenation, yields ethylene and acetylene or it may undergo scission of its carbon atoms and the products formed then react further with hydrogen to form methane. Ethylene polymerizes to 1-butene and 1-hexene or is dehydrogenated to acetylene. By reaction with liberated hydrogen ethylene is also converted into ethane, butane and hexane. Benzene through polymerization gives dihydrobiphenyls, and by dehydrogenation, diphenyl, or by depolymerization it may yield acetylene, which on reacting with liberated hydrogen produces ethylene and ethane.

Investigation of the effect of pressure[84] on the reaction brought out the following facts: With constant duration of discharge (1 hour) the percentage of methane reacting and of free hydrogen produced increased rapidly with decrease in pressure; (2) the proportion of liquid products formed also increased with decreasing pressures; and (3) appreciable quantities of unsaturated hydrocarbons were obtained only at pressures greater than 200 mm. When the pressure was kept constant and the duration of the discharge varied, it was observed that with methane a steady state of synthesis and decomposition of the hydrocarbon was attained after 20 minutes and that further action of the discharge resulted in an increased yield of liquid products and of hydrogen. This induction period of 20 minutes was not noted with ethylene, but if such a period did exist it must have been much shorter. In comparing the percentages of hydrocarbons which had reacted when subjected to the discharge for 1 hour, it was found that for methane this corresponded to about 23 per cent, for ethylene about 85 per cent, and for acetylene 100 per cent. In addition, during the condensation of acetylene it was noted that some of the hydrocarbon was hydrogenated, probably to ethane or ethylene.

Lind and Glockler[85] studied the action of a semi-corona discharge (using a central aluminum rod in a pyrex glass cylinder) on methane, ethane, propane, butane, and ethylene. They found that condensation to liquid and solid hydrocarbons occurred in every case. With saturated hydrocarbons, condensation is brought about by elimination of hydrogen and some methane. These reactions are of the general character of those produced in the same gases by α-radiation. The liquids obtained at the same temperatures from different hydrocarbons exhibited similar physical properties, but these properties could be varied by changing the temperature of the discharge regions and the traps in which the liquids were collected.

The liquids from the action of the silent discharge on butane were examined in some detail.[86] The apparatus consisted of twelve glass ozonizers connected in parallel, the voltage employed being 20,000 volts. Butane (5420 grams) was passed continuously through the apparatus for a period of 660 hours and 1041 cc. of a liquid condensate (density 0.804) were secured. This was equivalent to a 15.37 per cent conversion of the butane. The liquid was separated into 40 fractions by distillation (at various pressures), and these were light, medium, and very viscous oils. One of the light fractions (the larger portion of the light oils) possessed the following properties:

B.P.	110° to 114° C.
N^{20}	1.4021
D^{20}_{4}	0.708
Molecular weight	114.7
Carbon	84.55%
Hydrogen	15.45%
Empirical formula	$C_8H_{17.4}$
Unsaturation (by halogenation)	22.5 mole per cent

This fraction was recognized as a mixture of octane and octylenes.

It is of interest to note that this largest fraction of light oils consisted of 8-carbon-atom molecules which can be produced from butane by simple doubling according to the Lind[87] theory of ionic reactions. The reactions can be formulated as follows:

$$C_4H_{10} \longrightarrow C_4H_{10}^{+} + E \text{ (ionization)}$$
$$C_4H_{10} + C_4H_{10}^{+} \longrightarrow (C_4H_{10}.C_4H_{10}) + \text{ (clustering)}$$
$$(C_4H_{10}.C_4H_{10})^{+} + E \longrightarrow C_8H_{18} + H_2 \text{ (neutralization of the cluster and rearrangement of bonds)}$$

Becker[88] reported that paraffin hydrocarbons when subjected to a high-tension discharge in a Siemens ozonizing tube yielded hydrogen and higher paraffins. This general reaction may be represented by

$$C_nH_{2n+2} + C_mH_{2m+2} \longrightarrow C_{n+m}H_{2(n+m)} + H_2$$

Methane gave only a small proportion of liquid hydrocarbons. Under the same conditions unsaturated hydrocarbons were converted to mixtures of saturated hydrocarbons of high molecular weights. Cyclic compounds behaved in a complex manner, since mixtures of saturated and unsaturated hydrocarbons were formed from the degradation products of the original substances. For example, decahydronaphthalene yielded butane, small quantities of unsaturated hydrocarbons, and about 25 per cent of resinous products of high molecular weight.[89]

The production of lubricating oils with improved properties by subjecting mineral oils or mixtures of fatty and mineral oils to the action of silent electric discharges has been brought to commercial success at several places in Europe.[90] About 1906, de Hemptinne[90a] showed that viscous oils result from the treatment of fatty oils with such discharges. Researches were extended to the action of these discharges on mineral oils, similar changes being observed.[90b] The process was called voltolization and the various viscous products thus formed were called voltols, voltolized oils, or "Elektrion" oils. It is stated that voltolized oils show less change in viscosity with temperature (i.e., give flatter viscosity curves) than ordinary lubricating oils and do not differ appreciably in acid number, asphalt content or cold test; hence they have been employed (usually in admixture with ordinary lubricating oil) as substitutes for castor oil in airplane lubrication.[90c] According to Wolf,[90d] in the production the mineral oil is allowed to flow over aluminum electrodes where it is exposed to a high-frequency alternating current of 5000 volts, oxidation being prevented by an atmosphere of inert gas. Numerous modifications of this voltolization treatment have been suggested.[90e]

[90a] Various suggestions of de Hemptinne for treatment of oils with silent discharges are embraced in the following articles and patents: *Z. physik. Chem.*, 1897, 22, 360; *Chem. Soc. Abs.*, 1897,

Epner[91] suggested the manufacture of motor or power fuels by subjecting gaseous hydrocarbons to the prolonged action of an alternating current of high frequency and high tension. The liquids so made can then be rendered more stable chemically by hydrogenation.

Use of the corona discharge in vapor phase cracking is said to result in a greater yield of gasoline of higher antiknock value.[91a] The experimental plant in which this method was perfected had a small wire suspended in the reaction chamber as one electrode. The oil vapors were subjected to the action of a high tension alternating current discharge of frequency not exceeding 10,000 cycles per second.

The experiments of Jakowsky[92] indicated that the corona discharge (low frequency of 60 cycles) had no effect on vapor phase cracking below 600° C. Above this temperature, however, the use of a corona discharge gave a gasoline

with a higher percentage of unsaturated hydrocarbons. A larger proportion of fixed, or difficultly condensible, gases were obtained when a high-frequency discharge was employed. The discharge itself produced no cracking of the oil vapors. The increased cracking appeared due to precipitation of the hot oil vapors against the walls of the reaction chamber, and to the decrease in channelling of the vapors by the electric turbulence set up by the discharge.

THE DECOMPOSITION OF HYDROCARBONS BY OTHER FORMS OF ENERGY

Under this heading will be discussed briefly the decomposition of hydrocarbons by forms of energy other than those already mentioned. These include ultraviolet light, α-radiation, and excited mercury atoms.

Tolloczko[93] observed that methane was unaffected by light from a mercury vapor lamp. Ethane, however, yielded methane and hydrogen together with a small quantity of liquid condensate which analysis indicated to be a mixture of hydrocarbons, principally hexanes. Berthelot and Gaudechon[94] found that ethylene and acetylene were polymerized under these conditions. The former yielded a liquid, boiling below 100° C. and possessing a disagreeable odor. Acetylene gave a solid polymer, but no benzene or hydrogen. Allene, methylacetylene and isoprene are converted into white polymerides by radiation from the hot mercury arc.[95]

Kemula[96] reported that although no dissociation of methane takes place under radiation with a mercury-vapor lamp, under analogous conditions ethane yielded hydrogen, methane, butane, hexane and a small amount of unidentified saturated and unsaturated liquid hydrocarbons. The products of photolysis and their relative proportions varied with the duration of irradiation. The reaction was best represented by

$$\mathrm{nC_2H_6} \longrightarrow \mathrm{(n-1)H_2 + C_{2m}H_{4n+2}}\ \text{(liquid)}.$$

indicating that there is a volume contraction.

Experiments on the action of excited mercury atoms on pentane vapors were carried out by Frankenburger and Zell.[97] They found that the primary action consisted in a loosening of the C—H or C—C linkages. The liberated hydrogen atoms and free hydrocarbon radicals then underwent secondary reactions (1) with one another, in the presence of an inert (oxygen-free) atmosphere, to give hydrogen and higher and lower molecular weight hydrocarbons, and (2) in the presence of oxygen to form hydrogen peroxide and organic oxygenated compounds having $\mathrm{CH_3{\cdot}CO}$ and $\mathrm{CH_3{\cdot}C(OH)}$ groups.

This activation of the carbon-to-carbon or carbon-to-hydrogen linkages has also been observed with ethane.[98] This hydrocarbon, on irradiation with ultraviolet light in the presence of mercury vapors, gave butane, hexane and octane, together with some methane. The proportions of butane in the product varied directly with the rate of flow of gas and the pressure, and inversely as the temperature of the receiver. The rate of activation, however, was independent of the pressure or rate of flow, but depended exclusively on the intensity of radiation.

Attention has been directed toward the action of α-radiation on hydrocarbons, and it has been shown that even such stable hydrocarbons as methane can be

disrupted with the production of higher hydrocarbons. Mund and Koch[99] studied the action of radon on methane, ethane, ethylene and acetylene. They concluded that a reaction occurred with methane which resulted in diminishing the number of gaseous molecules. The substances formed were not identified. Ethane decomposed giving hydrogen and ethylene, the latter being converted to liquid or solid substances. Ethylene itself was slowly changed into liquid materials, and acetylene to a fine yellow-brown powder.

Lind and Bardwell,[100] in an extensive investigation of the action of α-radiation on saturated hydrocarbons, showed that ethane, propane and butane each condense to give higher hydrocarbons, which are gaseous, liquid or solid, and saturated or unsaturated. This condensation is preceded by the elimination of hydrogen and methane (in the approximate ratio of $5H_2:1CH_4$) from the hydrocarbon molecule. Analysis of the liquid products indicated the presence of a large proportion of unsaturated hydrocarbons, but no unsaturated hydrocarbons were found among the gaseous products. This was accounted for by the rapid polymerization (and therefore removal from the gas phase) of any unsaturated hydrocarbons formed. The higher the molecular weight of the paraffin the greater the yield of liquid materials, which were similar to those obtained by the action of the silent discharge. Methane also gave higher hydrocarbons, but the formation of these was accompanied by the elimination of hydrogen only.

The action of α-particles on acetylene was somewhat easier to determine and follow.[101] This hydrocarbon at ordinary temperatures and pressures polymerized to a light yellow powder, which in some respects resembled the material previously obtained by other workers employing different procedures.[102] Because of its insolubility in all solvents and of the negative results from x-ray examination, very little is known about this substance. Prolonged action of α-particles did give some hydrogen, but the indications were that it came from the solid polymer rather than from acetylene. The polymerization of acetylene was catalyzed by the presence of ions of inert gases, nitrogen and helium.[103] With ethylene the reactions were much more complicated, resulting in the formation of a liquid condensate and of gaseous methane, hydrogen and ethane.

The elimination of both hydrogen and methane and the formation of liquid products from unsaturated hydrocarbons by the action of α-particles was noted also by Heisig.[104] The hydrocarbons investigated were allene ($H_2C{=}C{=}CH_2$), allylene ($CH_3C{\equiv}CH$), dimethylacetylene ($CH_3C{\equiv}CCH_3$), 2-butene ($CH_3CH{=}CHCH_3$) and isoprene ($H_2C{=}CH{-}C(CH_3){=}CH_2$). From allene and allylene, however, the liquids were further changed into solids, this transformation occurring sooner with allylene. A heavy, viscous, rubbery mass was obtained from isoprene. In continuing this study,[105] it was further noted that propylene condensed to a light mobile liquid and slightly less hydrogen and methane were given off than from ethylene under similar conditions. Vinylacetylene, on the other hand, yielded a white solid (which became orange-colored on exposure to the action of α-particles) but practically no hydrogen or methane was evolved. Propylene and cyclopropane may also be polymerized, according to Heisig.

Methane, ethane, propane and butane undergo decomposition with the liberation of hydrogen when subjected to high speed electrons emitted from a Slach-

Leonard cathode-ray tube.[106] The number of hydrogen molecules was about ten times the number of electrons corresponding with the filament current. On the assumption that only one per cent of the electrons actually entered the reaction vessel, it was calculated that the number of ion pairs produced in the gas was of the same order of magnitude as the number of molecules reacting.

The effect of cathode-ray bombardment of hydrocarbons has been extended by Schoepfle and Fellows[107] to include many different types of these substances. Saturated hydrocarbons, both paraffinic and cyclic, yielded large quantities of gas, containing both hydrogen and methane. With increasing molecular weight, the quantity of gas as well as its methane content became less and the hydrogen content increased. For the same molecular weight, hydrocarbons possessing branched chain structures gave larger proportions of gas. Olefins, both open chain and cyclic, reacted in a similar manner, but the volume of gas evolved was less than from the corresponding saturated compounds. Aromatics gave very little gas, the amount becoming appreciable only from those having a number of side chains or fairly long ones, e.g., hexamethylbenzene or p-cymene. The action of these rays on petroleum oils, and waxes, also results in the formation of hydrogen and methane and other saturated gaseous hydrocarbons.[108] While the rate as well as the quantity of gases evolved depended to a large extent upon the source and degree of refinement, in general those petroleum products having the larger proportion of saturated hydrocarbons yielded more gas than those containing a high percentage of unsaturated hydrocarbons.

McLennan and Patrick[109] observed that ethylene, subjected to cathode rays, was converted to a liquid, which on continued bombardment gave hydrogen, acetylene and saturated hydrocarbons. The polymerization of acetylene to a solid material by β-rays from radium is described by Mund and Jungers.[110] When methane, ethane, ethylene, or acetylene is exposed to β-rays from radium emanation in a differential manometer, a change in volume is noted, which is probably due to polymerization, according to Mund and Koch.[111] Ethane and ethylene produce minute drops of a highly refractive liquid. From acetylene is obtained a voluminous brownish-yellow amorphous powder, each pair of ions causing the union of 26 molecules of acetylene. A method for refining hydrocarbons is based upon the action of α-, β-, x-, ultraviolet or infra-red rays.[112]

The synthesis of liquid hydrocarbons from gaseous carbon compounds (e.g., coke-oven gas, natural gas or cracking gas) by the action of rapidly moving electrons (β-rays), or the combined action of β- and x-rays, is suggested by Plauson.[113] The reaction may be assisted by rotating electric or electromagnetic fields and by a catalyst suspended in the reacting gases. In addition to hydrocarbons, ketones and alcohols are obtained if the gases contain water vapor.

Stewart and Olson[114] studied the decomposition of hydrocarbons by positive rays. They concluded that the decomposition is due to dissociation by the ionizing electrons or to the secondary reaction between ions and neutral molecules. Selective absorption of hydrocarbon ions by propane and butane was observed. Natural H-rays have been produced by Pavlovski[115] from the action of α-rays on paraffin.

The decomposition of a large number of hydrocarbons in the glow discharge has been reported by Linder and Davis,[116] who observed that the rate of gas evolution per unit of current increased with molecular weight. Furthermore, the proportion of insoluble residue increased with increasing ratio of carbon to hydrogen in the original hydrocarbon. Linder[117] also concluded, from experiments with n-decane vapor, that electrical conduction in gases may follow an electrochemical equivalency law similar to Faraday's law of electrolytic conduction in liquids, as the amount of reaction was found to be proportional to the current and independent of the voltage and vapor pressure.

The synthesis of acetylene from methane, or from a hydrocarbon mixture containing ethane, by direct-current glow discharges between unequally curved electrodes has been proposed.[118] The electrodes are arranged in a reaction chamber so that the cathode-fall space is approximately equal to the space between the electrodes. Hydrogen may be added to the reacting hydrocarbons. In the absence of hydrogen, diacetylene is one of the reaction products.

Chapter 10

Reactions of Hydrocarbons with Steam, Carbon Dioxide, and Ammonia

REACTIONS OF HYDROCARBONS WITH STEAM

When hydrocarbons are allowed to react with steam at high temperatures in the presence of catalysts they are transformed into hydrogen and oxides of carbon. The reactions of methane, the most resistant of the hydrocarbons, can be expressed by the following reversible equations:[1]

$$CH_4 + H_2O \rightleftharpoons CO + 3H_2$$
$$CH_4 + 2H_2O \rightleftharpoons CO_2 + 4H_2$$

These reactions are strictly reversible, the equilibrium depending upon temperature and pressure conditions. The reaction of methane and steam at high temperatures is the reverse of the methane synthesis (reduction of the oxides of carbon by hydrogen) of Sabatier and Senderens[2] which takes place at lower temperatures.

The reactions of the higher hydrocarbons may be conceived to occur by initial decomposition at high temperatures into carbon, hydrogen, and methane, followed by reaction of carbon and methane with steam according to the equations:

$$C + H_2O \longrightarrow CO + H_2$$
$$CH_4 + H_2O \rightleftharpoons CO + 3H_2$$

Whatever the mechanism of the process, the reactions of ethane, propane and other paraffin hydrocarbons with steam may be summarized in the equations:

$$C_2H_6 + 2H_2O \rightleftharpoons 2CO + 5H_2$$
$$C_3H_8 + 3H_2O \rightleftharpoons 3CO + 7H_2$$
$$\text{or, in general, } C_nH_{2n+2} + nH_2O \rightleftharpoons nCO + (2n + 1)H_2.$$

Some of these processes are also reversible and it is actually possible to synthesize higher hydrocarbons by reduction of carbon monoxide with hydrogen in the presence of certain catalysts in the neighborhood of 300° C.[3]

From an industrial point of view the chief interest of these reactions lies in the possibility of producing hydrogen from gaseous hydrocarbons, more particularly from methane, by its reaction with steam.[4] By this process considerably more hydrogen can be produced from a given quantity of methane, or hydrocarbon gas, than by purely thermal decomposition processes (described in Chapter 7). Thus, by thermal decomposition according to the equation, $CH_4 \rightarrow C + 2H_2$, one volume of methane ultimately gives two volumes of hydrogen, but by reaction with steam at high temperatures one volume of methane yields three volumes of hydrogen.[5]

[3] See, for example, Fischer and Tropsch, *Brennstoff-Chem.*, 1923, **4**, 193; *Chem. Abs.*, 1924, **18**, 349. Ellis, "Hydrogenation of Organic Substances," D. Van Nostrand Co., New York, 1930, 674.

[4] Attempts to produce methyl alcohol from methane and steam according to the reaction $CH_4 + H_2O \rightarrow CH_3OH + H_2$ have not met with much success. However, Dreyfus (British Patent 337,410, 1929; *Brit. Chem. Abs.* **B**, 1931, 194) reported obtaining methyl and other alcohols from methane and steam heated at 200° to 500° C. at 50 to 100 atmospheres pressure in the presence of catalysts such as potassium dichromate and zinc oxide, zinc chromate with cobalt oxide, or zinc chromate.

Lang[6] was one of the first to investigate the reaction between methane and steam, his apparatus consisting of a porcelain tube filled with lumps of porcelain and heated to a high temperature.[7] An excess of steam was used with methane and yielded oxides of carbon and hydrogen. Because of the inactivity of his contact materials, Lang obtained yields of the oxides of carbon not exceeding 10 per cent of the theoretical.

Mayer and Altmayer[8] calculated the proportions of the reactants in the equilibria,

$$CH_4 + H_2O \rightleftharpoons CO + 3H_2$$

and

$$CH_4 + 2H_2O \rightleftharpoons CO_2 + 4H_2$$

by Haber's[9] method. Tables 64 and 65 show their calculated equilibrium constants and concentrations for different temperatures at one atmosphere pressure:

[9] Haber, "Thermodynamik technischer Gasreaktionen," Munich, 1905. Translated by Lamb, Longmans, Green & Co., New York, 1908.

Neumann and Jacob[10] investigated these equilibria both practically and theoretically. Their main conclusions are in good agreement with those of Mayer and Altmayer and their practical results from methane and steam may now be considered in some detail. Using a nickel-magnesium oxide catalyst (6.6 grams of nickel and 45.0 grams of magnesium oxide) and a gas mixture of 43 per cent methane and 57 per cent steam the results in Table 66 were obtained. The gas rate in all runs was 5 cc. per minute.

TABLE 66.—*Reaction of 43% Methane and 57% Steam.*

1040	0.1	19.4	0.4	58.8	21.3

Neumann and Jacob concluded that at moderate temperatures (about 600° C.) both reactions tend to occur simultaneously. At high temperatures the reaction producing carbon monoxide predominates probably because of the decomposition of the carbon dioxide formed by the other reaction:

$$CH_4 + CO_2 \longrightarrow 2CO + 2H_2$$

Even with an excess of steam at very high temperatures the composition of the resulting gases may be expressed by the equation:

$$CH_4 + H_2O \rightleftharpoons CO + 3H_2$$

The experimental results of Neumann and Jacob for this reaction are in good agreement with the values calculated from the following equation, deduced from free energy data:

$$\log K_p = \frac{-10308}{T} + 4.87 \log T + 0.000066\,T - 0.000000081\,T^2 - 3.04$$

$$\text{where } K_p = \frac{p_{CO} \times p^3_{H_2}}{p_{CH_4} \times p_{H_2O}}$$

---

[10] *Z. Elektrochem.*, 1924, 30, 557; *Chem. Soc. Abs.*, 1925, 128 (2), 532.

Pease and Chesebro[11] determined the equilibrium constant of the reaction $CH_4 + 2H_2O \rightleftharpoons CO_2 + 4H_2$ at temperatures of about 500° C. Equilibrium was approached from both directions. At 505° C. the value of the constant was found to be 0.037 (the partial pressures of the reactants and products being expressed in atmospheres). These investigators also pointed out that two other reactions,

$$\begin{aligned} CH_4 + H_2O &\longrightarrow CO + 3H_2 \\ \text{and } CO_2 + H_2 &\longrightarrow CO + H_2O \end{aligned}$$

must be taken into account at higher temperatures.

The equilibrium constant, K_p, of the reaction

$$CH_4 + 2H_2O \rightleftharpoons CO_2 + 4H_2$$

may also be calculated from the following equation, deduced by Lewis and Randall[12] from free energy data:

$$\log K_p = \frac{-8100}{T} + 3.96 \log T + 0.00104\,T - 0.00000023\,T^2 - 3.15$$

$$\text{in which } K_p = \frac{p_{CO_2} \times p^4{}_{H_2O}}{p_{CH_4} \times p^2{}_{H_2O}}$$

The catalytic conversion of methane to hydrogen and oxides of carbon has been investigated by Gluud and his collaborators,[13] who found that the conversion takes place satisfactorily in the presence of a nickel catalyst supported on special refractory materials which, unlike many other materials tried, do not promote the formation of soot. In applying the process to gases containing sulphur, it was observed that the nickel catalyst is gradually poisoned by the formation of nickel sulphide but that its activity can be restored by oxidation with steam. Soot formation, which is likely to occur during the preheating of the methane, was avoided by rapid heating of the gases following the addition of small proportions of air. The observation that the activity of the catalyst is seriously reduced by the presence of sulphur compounds conflicts with the results of Fischer and Tropsch.[14] They investigated the reactions of methane with both steam and carbon dioxide in the temperature range 840° to 920° C. in a small externally heated laboratory reaction tube in the presence of a number of catalysts. These investigators found that the best catalysts, consisting of nickel or cobalt promoted with alumina and supported on refractory materials, are not seriously injured by the presence of sulphur compounds in the gas used. Though the initial conversions were higher than those obtained after the catalyst had been in use for some time, the loss of activity soon ceased and was succeeded by an apparently indefinite period of constant activity. Goodfellow and Spencer[14a] observed that chromium catalysts are activated by adding about 1 per cent of hydrogen sulphide (or other gaseous sulphur compounds) to the reacting gases.

A cyclic process for catalytically converting methane, or gases containing methane, into carbon monoxide and hydrogen by reaction with steam has been described by Hawk, Golden, Storch and Fieldner.[15] The catalysts used in this work were prepared by depositing the nitrates of nickel, cobalt or aluminum, or nickel and aluminum, on small pieces of porous refractory material, heating the nitrates for several hours at 250° to 300° C. to convert them to the oxides, and finally reducing the oxides by heating first slowly to 700° C. and then rapidly to 1060° to 1150° C. in the presence of a mixture of natural gas and insufficient air for complete combustion. Of the catalysts so prepared the nickel catalyst was found to be the most effective; the nickel-aluminum [15a] and cobalt catalysts were unsatisfactory.

The optimum temperatures for the reaction were from 900° C. to 1000° C., and in this range almost theoretical conversion was obtained. As the ratio of steam to methane was increased, however, larger quantities of carbon dioxide were obtained without decreasing the percentage of methane converted.

These investigators also calculated the free energy and equilibrium constants for the reaction between methane and steam from the data of Eastman [16] and Storch.[17] The values are given in Table 68.

TABLE 68.—*Free Energy and Equilibrium Constants for Reaction between Methane and Steam.*

K_p	150.5	1296	7940

$$\Delta F \text{ represents the free energy and } K_p = \frac{p_{CO} \times p^3_{H_2}}{p_{CH_4} \times p_{H_2O}}$$

Almost complete reaction between methane and steam at temperatures of 850° C. in the presence of reduced nickel oxide was obtained by Klyukvin and Klyukvina.[18] The reaction, however, was retarded by the addition of aluminum oxide to the nickel catalyst. Activated vegetable carbon gave 100 per cent conversion of the methane, although the primary reaction was accompanied by another reaction, namely that between carbon and steam:

$$C + 2H_2O \rightleftharpoons CO_2 + 2H_2$$

The same catalysts could be used for the reaction between methane and carbon dioxide.

According to Kubota and Yamanaka [19] certain metallic oxides (alumina, zirconia, thoria, beryllia, chromium oxide, ferric oxide, ceria, or magnesia) activate a nickel catalyst in decomposing methane by steam at about 1000° C. The activation effects of these oxides are very marked with a ratio of 100 atoms of nickel to 1 molecule of the added oxide. Alumina gives a large proportion of carbon dioxide, and magnesia, a large proportion of carbon monoxide. In the presence of a nickel-aluminum oxide-potassium carbonate catalyst, methane was rapidly and completely decomposed by steam into hydrogen and carbon dioxide at 650° C.[19a]

A study of catalysts for producing hydrogen from natural gas and water vapor has been made by Patryn and Ziolkowski.[20] Reduced iron, nickel, and cobalt deposited on asbestos, oxides of these metals, and mixtures of these reduced metals were tried. Their work can be summarized as follows: Best hydrogen yields are obtained with reduced nickel at 350° to 550° C. with 1 volume of methane to 10 volumes of water vapor. Iron and cobalt are immediately oxidized on contact with water vapor. The oxides of these metals act as catalysts only at temperatures above 800° C. Mixtures of nickel, iron and cobalt were found to be poorer catalysts than nickel alone. Of the three, nickel is the most resistant to oxidation by water vapor. This resistance can be raised by the addition of a difficultly reducible oxide (oxide of aluminum, manganese, chromium, zinc or potassium). A mixture of 20 per cent alumina and 80 per cent of reduced nickel gave the best results with 5 volumes of water vapor and 1 volume of methane. A gas mixture, typical of that obtained with a nickel catalyst in this process, is given in Column I of the table below. Column II gives the composition of the same gas after being washed with alkali. Column III shows the result obtained by processing the mixture a second time.

REACTIONS OF HYDROCARBONS WITH CARBON DIOXIDE

Hydrocarbons react with carbon dioxide at high temperatures in the presence of catalysts to yield mixtures of carbon monoxide and hydrogen.[21] The reaction of methane, which was observed in 1888 by Lang,[22] can be represented by the equation:

$$CH_4 + CO_2 \rightleftharpoons 2CO + 2H_2$$

Mayer and Altmayer [23] calculated the equilibrium concentrations of these reactants at different temperatures under 1 atmosphere pressure, using Haber's method, with the results in Table 69.

TABLE 69.—*Equilibrium:* $CO_2 + CH_4 \rightleftharpoons 2CO + 2H_2$.

Temp. ° Absolute	CO	H_2	CO_2	CH_4
	Per Cent			
700	3.44	3.44	46.56	46.56
800	12.83	12.83	37.17	37.17
900	29.44	29.44	20.56	20.56
1000	43.06	43.06	6.94	6.94
1100	48.10	48.10	1.90	1.90

Fischer and Tropsch [24] investigated the effects of various catalysts on this reaction. The best catalyst was found to be nickel with alumina as a promoter supported on clay fragments. Cobalt proved as active as nickel and its activity is increased by the presence of alumina. Copper, iron and molybdenum were not active as catalysts.

[21] The possibility of producing alcohols, aldehydes, ketones, acids and esters by the reaction of carbon dioxide and hydrocarbons is discussed in Chapter 42.

[22] *Z. physik. Chem.*, 1888, **2**, 161; *Chem. Soc. Abs.*, 1888, **54**, 1029. Berthelot (*Bull. soc. chim.*, 1870, (2) **13**, 9; *Chem. Zentr.*, 1870, 216) attempted to produce a reaction between methane (as well as ethane) and carbon dioxide in sunlight and in sealed tubes at 100° and 200° C. for 20 hours. No changes were observed.

[23] *J. Gasbel.*, 1909, **52**, 326; *Chem. Soc. Abs.*, 1909, **96** (1), 753.

[24] *Brennstoff-Chem.*, 1928, **9**, 39; *Chem. Abs.*, 1928, **22**, 2652.

Klyukvin and Klyukvina[25] recorded experiments in which an equimolecular mixture of carbon dioxide and methane was passed at 1000° C. with a time of contact of approximately 38 seconds (I) through an empty porcelain tube, (II) through an empty iron tube, and (III) over a reduced nickel catalyst. The conversions of methane into carbon monoxide and hydrogen were (I) 43 per cent, (II) 58 per cent, and (III) 97.6 per cent, respectively. With an active nickel catalyst (III), the gaseous reaction products consisted of 47 per cent of carbon monoxide, 48.6 per cent of hydrogen, 2.6 per cent of nitrogen, and no by-products.

Fischer and Pichler[26] studied the carbon dioxide-methane reaction in the presence of a nickel catalyst at various temperatures under atmospheric and subatmospheric pressures. Reduction of pressure below atmospheric is so favorable to this reaction (as might be expected from theoretical considerations) that complete conversion could be effected at 500° to 600° C. under 0.01 atmosphere pressure, whereas a temperature of 900° C. was required to secure the same result at 1 atmosphere.[27] At lower pressures the reaction could be carried almost to completion at even lower temperatures. The reaction velocity increased in inverse ratio to the pressure.

Peters and Pranschke[28] showed that the reaction between methane and steam, or methane and carbon dioxide, can be carried almost to completion by subjecting the gas mixture at high rates of flow to a high-voltage electric discharge at pressures below atmospheric. The optimum voltage is 5000 to 6000 volts. At lower voltages a considerable part of the methane is converted into acetylene.

Hawk, Golden, Storch and Fieldner[29] pointed out that between 800° and 1000° C. the reaction between methane and carbon dioxide proceeds to approximately the same extent as that between methane and steam. The free energy and equilibrium constants for the first, as calculated by these workers, are:

TABLE 70.—*Free Energy and Equilibrium Constants for Reaction between Methane and Carbon Dioxide.*

$T°$ Absolute	1073	1173	1273
ΔF	−11,251	−18,112	−24,943
K_p	194.8	2,353	18,990

where ΔF represents free energy, and $K_p = \dfrac{p^2_{CO} \times p^2_{H_2}}{p_{CH_4} \times p_{CO_2}}$

The change of equilibrium with temperature in the reaction between methane and carbon dioxide can be deduced from free energy data and is represented by the equation:

$$\log K_p = \frac{-12450}{T} + 7.59 \log T - 0.00236\,T + 0.000000068\,T^2 - 6.64$$

where $K_p = \dfrac{p^2_{CO} \times p^2_{H_2}}{p_{CH_4} \times p_{CO_2}}$

Later, Storch and Golden[29a] observed that, at 1500° C. and a time of contact of 0.03 to 0.04 second, a mixture of methane (25 per cent) and carbon dioxide

[29a] *Ind. Eng. Chem.*, 1933, 25, 768.

(75 per cent) yielded about 10 per cent of unsaturated hydrocarbons (principally acetylene), 10 per cent carbon monoxide, 35 per cent hydrogen and 45 per cent unchanged methane. With somewhat longer times of contact the percentage of hydrogen and carbon monoxide increased, the percentage of unsaturated hydrocarbons remaining approximately constant. At this high temperature steam was less desirable as a diluent than carbon dioxide because of the loss of methane as carbon which deposited in the reaction tube. With carbon dioxide this loss amounted to only a few per cent, though with steam it increased to 15 to 20 per cent.

Schmidt and Neumann[30] studied the equilibrium constants of this reaction at temperatures from 500° to 800° C. using nickel supported on silica gel. They found an agreement between the observed methane transformation and that calculated from free-energy data at temperatures above 600° C. Below 600° C., however, the methane converted was greater than that deduced from the free-energy data. This difference is attributed to two side-reactions:

$$CO_2 + H_2 \longrightarrow CO + H_2O$$

followed by

$$H_2O + CH_4 \longrightarrow CO + 3H_2$$

Industrial Applications of the Reactions of Steam and Carbon Dioxide with Hydrocarbons

From the above review of the catalytic reaction of methane with steam, it is clear that hydrogen may be produced in accordance with the following two equations:

$$(1)\ CH_4 + H_2O \longrightarrow CO + 3H_2 - 48.9 \text{ kg. cals.}$$

$$(2)\ CH_4 + 2H_2O \longrightarrow CO_2 + 4H_2 - 38.5 \text{ kg. cals.}$$

Since the first reaction produces 3 volumes of hydrogen, and the second 4 volumes of hydrogen, per unit volume of methane reacting, it is evident that these are superior to the purely thermal decomposition of methane for hydrogen production. Moreover, both reactions can be efficiently catalyzed. The catalysts have a long life and can be easily revivified.

Of these reactions, the first, which produces a mixture of carbon monoxide and hydrogen in the molar ratio of 1:3, can be carried almost to completion at sufficiently high temperatures (over 900° C.). The resulting mixture of carbon monoxide and hydrocarbon can be utilized, after an adjustment of the proportions of these two gases, in the synthesis of methanol. On the other hand, where the production of pure hydrogen is desired, it is advantageous to subject the gas mixture to a further reaction with steam (at a lower temperature (500° C.) in the presence of a catalyst) to convert carbon monoxide into carbon dioxide according to the well-known water-gas equilibrium:[31]

$$(3)\ CO + H_2O \rightleftharpoons CO_2 + H_2$$

By conducting the steam reaction in these two stages, one volume of methane yields a mixture of 4 volumes of hydrogen and 1 volume of carbon dioxide, from which the latter can be easily eliminated either by absorption in an alkaline liquid or by washing with water under pressure.

---

[30] *Z. Elektrochem.*, 1932, **38**, 925; *Chem. Abs.*, 1933, **27**, 1260.

[31] The water-gas reaction can be successfully operated to yield a gas containing only small proportions of carbon dioxide by using excess of steam at about 530° C. in the presence of catalysts, such as iron-alumina, (Evans and Newton, *Ind. Eng. Chem.*, 1926, **18**, 513), dolomite (Gluud, *Ber. Ges. Kohlentechnik*, 1930, **3**, 211; Klempt and Brodkorb, *ibid.*, 1930, **3**, 261), and other catalysts (see Taylor, "Industrial Hydrogen," Chemical Catalog Co., Inc., New York, 1921, 158). See also Chapter 7.

A similar result is obtained by carrying out the methane-steam reaction according to equation (2) (see above). Unfortunately, it is impossible to conduct this reaction in such a way as to obviate the simultaneous occurrence of the reaction of equation (1), which produces carbon monoxide. By operating at temperatures of the order of 500° to 600° C. with sufficiently active catalysts and an excess of steam, reaction (2) can be made the preponderant one. The proportion of steam required to suppress the carbon monoxide reaction to desired limits is high, and difficulties are likely to be encountered through poisoning of the catalysts by carbon deposition and because of the necessity of using much longer time of contact.[32] As the reaction temperature is raised the equilibrium is shifted more and more to favor carbon monoxide production and the reaction of equation (1) becomes increasingly important even in the presence of excess steam. It has been found that the relative amounts of carbon monoxide and carbon dioxide formed at various reaction temperatures and steam ratios are in good agreement with those demanded by the water-gas equilibrium. These considerations lead to the belief that probably the best method of utilizing the steam-methane reaction for the production of hydrogen is in a two-stage process involving first the catalytic reaction at high temperature according to equation (1), followed by further treatment with steam at lower temperatures in the presence of a catalyst for the water-gas reaction. This yields ultimately a gas mixture containing about 20 per cent carbon dioxide and 80 per cent hydrogen with only traces of methane and carbon monoxide.

In carrying out the reaction of methane with steam at high temperatures to yield hydrogen and carbon monoxide, catalysts of nickel supported on inert refractory material appear to be best. Evidence regarding the life of such catalysts is somewhat conflicting but it appears that sulphur compounds in the gas are likely to cause a decline in activity. According to Neumann and Jacob,[33] the deposition of free carbon on the catalyst is likely to occur under certain circumstances, particularly when the gases contain appreciable proportions of homologues of methane. Deposition of free carbon causes rapid deterioration of the catalyst and necessitates frequent revivification. To minimize this, an excess of steam would seem advantageous. However, Hawk, Golden, Storch and Fieldner [34] observed that an increase in the steam concentration in the reacting gases promotes the formation of more carbon dioxide at the expense of carbon monoxide without increasing the fraction of methane converted.

Perhaps the main technical difficulty associated with the application of this reaction is the highly endothermic nature of the process,

$$CH_4 + H_2O \longrightarrow CO + 3H_2 - 48.9 \text{ kg. cals.},$$

combined with the high temperature necessary for complete reaction. The difficulties involved in the external heating of large catalytic units, into which much heat energy must be introduced at a high temperature level, are very great. This difficulty has been overcome in some processes [35] by applying internal heating to the reacting system through the exothermic oxidation of methane according to the equation:

---

[32] Hirsch (*Bull. Mem. Soc. Ing. Civ. France*, 1932, 85, 286; *Brit. Chem. Abs.* B, 1932, 919) has also studied these conditions which influence the conversion of natural and coke-oven gas into hydrogen.

[33] *Z. Elektrochem.*, 1924, 30, 557; *Chem. Soc. Abs.*, 1925, 128 (2), 532.

[34] *Loc. cit.*

[35] See, for example, Pictet, British Patent 24,256, 1910; *J.S.C.I.*, 1911, 30, 1044.

$$CH_4 + \tfrac{1}{2}O_2 \longrightarrow CO + 2H_2 + 7{,}000 \text{ cals.}$$

To accomplish this, a mixture of methane, steam and oxygen is passed through the catalyst chamber. Unless high proportions of oxygen are employed, however, the exothermic oxidation reaction will not provide sufficient heat to counterbalance the endothermic methane-steam reaction and, in general, it will be necessary to apply external heat to the reaction chamber in addition. If air is used instead of oxygen, the resulting gas will contain nitrogen and, by adjustment of the proportions of the constituents, a mixture suitable for the ammonia synthesis may be obtained.

According to Hawk, Golden, Storch and Fieldner, the use of air or oxygen in the reacting system often introduces another difficulty. Certain activated nickel catalysts are poisoned by oxygen, probably on account of the formation of a protective film of oxide, but apparently this difficulty was not experienced by these investigators, who supplied the heat of reaction directly by alternately blasting the catalyst bed with a gas-air mixture and introducing the methane-steam mixture. It was found possible to prepare catalysts which were uninjured by this treatment even when burned with a moderate excess of oxygen on the catalytic surface.

Instead of effecting the reaction of the mixture of methane, steam and air (or oxygen) in a single step in the presence of the catalyst, the process may be operated in two stages. In the first of these the exothermic oxidation reaction is utilized to heat the gaseous mixture and in a second stage the methane-steam reaction is allowed to proceed in the presence of the catalyst. This method avoids poisoning of the catalyst by free oxygen.

In another process[36] steam and methane are passed through progressively hotter zones to complete reaction and the products are passed into progressively cooler zones where air or a mixture of air and oxygen is added to oxidize carbon monoxide to carbon dioxide. A mixture of nitrogen and hydrogen is obtainable in this way which can be used after the separation of CO_2 for the synthesis of ammonia. Gases from the distillation or gasification of fuel may be passed with steam at 200° to 600° C. under pressure over such catalysts as ferrous oxide, nickel, bismuth, lead, or metals of the copper group.[37]

The methane-steam reaction is utilized for the production of hydrogen by the Standard Oil Company of New Jersey. A two-stage process is employed, in the first of which the reaction

$$CH_4 + H_2O \longrightarrow CO + 3H_2$$

is carried out in the presence of catalysts at about 870° C. (1600° F.). In this step cracking gases and steam are used. A further reaction with steam in the presence of a catalyst at 455° C. (850° F.) converts the carbon monoxide into carbon dioxide and yields more hydrogen. No technical details of the plant or of the operating conditions used have been published. The gaseous mixture leaving the final stage contains 79 per cent of hydrogen, 20 per cent of carbon dioxide, and 1 per cent of other gases. Carbon dioxide is removed, after compression to 240 pounds per square inch pressure, by washing with water and subsequently scrubbing in a bubble plate tower with aqueous triethanolamine to remove the last traces. The gas, containing over 97 per cent hydrogen, is compressed to 3600 pounds per square inch for use in the hydrogenation of oil.[38]

[36] Hydro-Nitro S. A., French Patent 723,817, 1931; *Chem. Abs.*, 1932, **26**, 4823. British Patent 390.849, 1931; *Brit. Chem. Abs.* **B**, 1933, 534. See also I. G. Farbenindustrie A.-G., British Patent 364,106, 1930; *Brit. Chem. Abs.* **B**, 1932, 248.

[37] Hydro-Nitro S. A., French Patent 724,825, 1930; *Chem. Abs.*, 1932, **26**, 4922.

Gross[39] gasified fuels with a mixture of oxygen, air, and water vapor to convert the hydrocarbons into carbon monoxide and hydrogen. The air content can be adjusted to produce a gas mixture for conversion to ammonia.

Geisenberger[40] generated hydrogen mixed with carbon monoxide or dioxide by heating light hydrocarbons or other carbonaceous materials, such as bitumen, shale, beeswax, or turpentine, with steam in a retort. Rose[41] passed superheated steam and a hydrocarbon mixture through a refractory tube heated to 1200° C. to obtain a gaseous fuel.

Gluud and others[42] suggested a process of technical interest. In large-scale experiments using a mixture of methane, steam, and air to supply a mixture of nitrogen, carbon monoxide, and hydrogen, they showed that the process could be carried out satisfactorily in an externally heated converter. This was constructed of a heat-resisting alloy (20 per cent nickel, 25 per cent chromium, and 55 per cent iron).[43] The mixture of gas with regulated amounts of air and steam was passed upward through a cylindrical column (94 cm. long and 12 cm. in diameter) of catalyst consisting of nickel supported on a refractory carrier. The results obtained in this plant are exemplified by the treatment of a coal distillation gas containing 6 per cent carbon monoxide, 26 per cent methane, 55 per cent hydrogen, and 8 per cent nitrogen. Passing 6 cubic meters of this gas mixed with 3 kilograms of steam and 3 cubic meters of air per hour over the above volume of catalyst at about 1050° C. produced a gas mixture consisting of 2 per cent carbon dioxide, 17 per cent carbon monoxide, 56.5 per cent hydrogen, and 24.5 per cent nitrogen with only traces of methane.

Without air only about 3.5 cubic meters of coal distillation gas per hour could be converted into a methane-free product with this equipment. By introducing air into the reacting gas mixture at proper intervals in the catalyst bed, the methane content of the gaseous products could be reduced to 0.03 to 0.09 per cent. The gaseous products of this high-temperature treatment were subsequently subjected to further reaction with steam at lower temperatures in the presence of a catalyst for the water-gas reaction (dolomite) and practically all the carbon monoxide could thus be converted into carbon dioxide. The carbon monoxide content of the product could be reduced to about 0.05 to 0.07 per cent by volume.

The technical application of the reaction between methane and carbon dioxide,

$$CH_4 + CO_2 \longrightarrow 2CO + 2H_2,$$

is beset by the same difficulties encountered in the reaction between steam and methane at high temperatures. Both reactions can only be carried to completion at high temperatures (1000° C. and over) and both are highly endothermic. The methane-carbon dioxide reaction is catalyzed by the same catalysts effective in the methane-steam reaction.

Pictet[44] suggested the decomposition of petroleum vapors in such a way that carbon, instead of being deposited, is converted into carbon monoxide by the action of steam. By admitting a regulated quantity of oxygen, so that the combination of the oxygen with the carbon provides all the heat required for the reaction, it is then only necessary to heat the hydrocarbons initially to their temperature of dissociation. Water and hydrocarbon alone, when fed into an iron tube about 3 to 4 meters long heated at 1350° C., yield hydrogen and carbon monoxide. However, if oxygen is added to the mixture the temperature of the tube may be reduced to 1200° C.[45] In generating hydrogen from hydrocarbons, Tyrer[46] added only a limited proportion of steam to the reacting mixture to render the process independent of external heat.

It has been proposed also to pass hydrocarbon gases through an apparatus consisting of non-combustible checker material heated to a temperature high enough to decompose the hydrocarbons, and simultaneously to introduce steam. In this manner reaction is effected and gas consisting essentially of hydrogen and carbon monoxide, in the ratio of 2:1 or 3:1, is obtained.[47]

Dieffenbach and Moldenhauer[48] have recommended a process for the production of hydrogen by the reaction of steam with hydrocarbons, or their oxygenated derivatives, at high temperatures. The mixture is heated to a moderate temperature, or kept in contact with the catalytic surface for such a short time that, simultaneously with hydrogen, only carbon dioxide is produced. From the resulting mixture of hydrogen and carbon dioxide the latter may be removed easily, leaving more or less pure hydrogen. As catalysts, wire gauzes of nickel, cobalt or platinum, disposed transversely to the direction of flow of the gases and heated electrically, are suggested.

Dibdin and Woltereck[49] obtained an illuminating and heating gas by passing a mixture of paraffin hydrocarbons and superheated steam over a porous spongy contact agent such as ferroso-ferric oxide.

Mittasch and Schneider[50] developed a process for the production of hydrogen by the interaction of hydrocarbons and steam in the presence of a nickel catalyst at temperatures of 800° to 1000° C. The nickel may be supported by refractory material (ignited magnesium oxide). Besides gases, liquid or solid hydrocarbons or gas mixtures containing hydrocarbons, such as coal gas, may be used. The nickel may be mixed with other metals or metallic oxides. The process may be carried out in such a manner that alternately hydrocarbon-air and hydrocarbon-steam mixtures are passed through the reaction chamber. The resulting gas mixture is subjected to the further action of steam at lower temperatures to convert the carbon monoxide into dioxide. In a related process[51] carbon dioxide is substituted, either partly or completely, for steam and the reaction carried out at 900° to 1100° C. Under such conditions natural gas containing 90 per cent of methane is rapidly converted into a mixture of hydrogen and carbon monoxide by reaction with 3 to 4 times its volume of carbon dioxide.[52]

The use of a nickel catalyst with promoters (the oxides of titanium, cerium, zinc, molybdenum, chromium, beryllium, uranium, zirconium, manganese, cadmium, calcium and other metals) at temperatures below 700° C. has been proposed by Williams.[53] The catalysts are prepared from the nitrates of the metals which should be free of chlorides and sulphides as these two classes of compounds poison the catalyst. The addition of salts of the rare earth metals, particularly those belonging to the cerium group, is recommended by Chaffette.[54] One method of preparing a catalyst from nickel nitrate has been described by Al[55] and consists in treating the nitrate with somewhat less than the theoretical quantity of sodium hydroxide, followed by reduction of the nickel compound so formed with hydrogen.

Magnesium oxide, impregnated with the oxides of nickel, cerium, or aluminum, has also been suggested.[56] Since the carbon dioxide formed during the reaction between the hydrocarbons and steam is absorbed by the magnesium oxide it is necessary occasionally to regenerate the catalyst by calcining to expel the carbon dioxide. The use of calcium or cerous oxide has also been recommended by others.[57] Cerous oxide absorbs carbon dioxide at 100° C. and can be regenerated by heating the resulting carbonate to 350° to 500° C.

Bergius[58] described a method for the production of hydrogen (for hydrogenation purposes) from gases containing methane (especially from the waste gas from hydrogenation processes) by treatment with steam at 1100° C. In a second stage carbon monoxide is converted to dioxide by reaction with more steam at a lower temperature.

The decomposition of hydrocarbon mixtures with air and steam in the presence of an iron-chromium alloy at high temperatures (1200° to 1300° C.) has been proposed by Clancy.[59]

Casale[60] described a process for the conversion of methane into carbon monoxide and hydrogen by passing a mixture of methane, steam and oxygen through a reaction chamber maintained at 1100° to 1300° C. According to Casale, industrial success with this reaction will be obtained only when conditions in the reaction chamber are such that the final concentration of methane is practically nil. These conditions are said to be realized when the system of the reacting gases: (1) is maintained at pressures below atmospheric; (2) attains a temperature of above 1000° C.; and (3) contains a large excess of steam above that required for reaction.

A process has been proposed by Schmidt and Niemann[61] in which hydrocarbons, alone or mixed with other gases not containing free oxygen, are treated with steam at 300° to 600° C. in the presence of nickel, cobalt or iron activated with difficultly reducible oxides of chromium, vanadium, potassium, magnesium, aluminum, or alkaline earth metals. The reaction may be performed in stages by transforming some of the hydrocarbons, removing the carbon dioxide, and repeating the succession of operations with the hydrogen-hydrocarbon mixture until all the hydrocarbons have been converted. Porter[62] similarly treated a hydrocarbon gas with steam, and after removing the reaction products, subjected them to further treatment with another body of catalyst.

In another method of decomposing hydrocarbons with water vapor,[63] the hot gases after reaction are cooled by water. The water which thus becomes heated is brought into contact with fresh hydrocarbon gases which, thus saturated with water vapor, are introduced into the decomposition chamber.

The production of hydrogen from hydrocarbons, particularly methane, and steam (preferably in excess) by allowing the heated gases to react in successive stages in the presence of catalysts has also been suggested by the Union Chimique Belge, Soc. Anon.[64]

Blake[65] developed a process in which methane and steam in proper proportions are allowed to react in the presence of a catalyst, such as nickel-ceria-alumina, at temperatures ranging from 400° C. to 700° C. to produce hydrogen and carbon dioxide with little or no carbon monoxide. Thus, using 10 volumes of steam to 5 volumes of CH_4 at 508° C., a 90 per cent conversion of the methane was observed and the dry gaseous products contained only 2 per cent of carbon monoxide (after removal of CO_2).

Unsaturated hydrocarbons in a gas mixture which is to be used for the production of hydrogen are reduced by Williams[66] in a prior catalytic treatment with hydrogen or by adding hydrogen to the mixture and allowing the reduction to proceed simultaneously with the decomposition. For the reaction with steam, nickel chromate is used.

Burwell[67] suggested heating hydrocarbons and steam at 1050° to 1150° C. to produce a mixture of hydrogen, carbon monoxide, carbon and hydrocarbons. Carbon is removed by settling and liquid hydrocarbons by scrubbing with water. Hydrocarbons, similar to methane, are converted into carbon monoxide and hydrogen by heating the moist mixture at 1230° to 1280° C., carbon monoxide being converted into dioxide by adding an excess of oxygen to the dried gases and passing them over manganese dioxide catalyst below 100° C. Any oxygen remaining is removed by passing the gases over heated copper, and carbon dioxide is absorbed in solutions of caustic alkalies.

Mixtures of air, oxygen, or carbon dioxide, and steam, with gaseous, liquid or solid carbonaceous materials may be made to react in an electric arc.[68] The gas mixtures thus obtained are further treated with steam, the carbon monoxide reacting to yield hydrogen and carbon dioxide. The carbon dioxide and other impurities are then removed from the product. A mixture of nitrogen and hydrogen which may be used for the synthesis of ammonia is obtained by using air as the oxidizing agent and subsequently adding hydrogen (prepared, for example, by a similar process using carbon dioxide instead of air) to adjust the mixture to the correct proportions. By passing gas mixtures containing hydrocarbons through an electric arc, or by incompletely oxidizing them, they are converted to unsaturated hydrocarbons. After removal of the unsaturated hydrocarbons, the resulting gases can be heated with steam to obtain a mixture of hydrogen and carbon monoxide.[69]

It has also been proposed[70] to pass a mixture of 1.8 parts of methane, 2.8 parts of air, and 0.6 part of carbon dioxide through an electric arc of 2.6 amperes at 1,400 volts. The products are treated with steam in the presence of nickel and the carbon dioxide, produced by the conversion of the carbon monoxide, is removed by absorption. The resulting hydrogen-nitrogen mixture is in the correct proportion for the synthesis of ammonia.

Another procedure[71] is that of treating methane with steam in proportions and under conditions such that the resulting gases contain 2 to 15 per cent (best about 4 to 5 per cent) of unchanged methane. The methane is subsequently removed (for example, by combustion with oxygen or along with carbon dioxide by extraction with gasoline under pressure). Elimination of the carbon monoxide from the products may be facilitated by converting the greater part of it, prior to the removal of the undesired gases, into carbon dioxide and hydrogen by reaction with steam. The remainder may be converted to methane by catalytic reduction and removed.

A process for the manufacture of carbon monoxide and hydrogen by oxidizing hydrocarbons (for example, methane) with steam and air in a reaction chamber in the absence of catalysts has been reported by the Union Chimique Belge, Soc. Anon.[72] Pallemaerts[73] suggested preheating the air and gas in separate chambers. The I. G. Farbenindustrie A.-G.[74] proposed to conduct the reaction of methane with air and steam in a water-gas producer in which coal or coke is being gasified at 800° to 1000° C.

Several methods have been described for the production of hydrogen from hydrocarbon gases, particularly refinery gases containing 2 to 10 per cent of unsaturated gases and freed from the major portion of the sulphur compounds originally present. The hydrocarbon gas is passed with an excess of steam through an elongated catalytic zone at high temperatures (650° to about 1100° C.), the direction of flow of the gas mixture being periodically reversed. The reactants are then passed to a second reaction zone where the carbon monoxide is converted by reaction with more steam into carbon dioxide and hydrogen.[75] The catalyst (nickel, or an oxide of nickel and alumina) used in the first stage of the process at temperatures above 650° C. may be reactivated by passing steam, free from hydrocarbon gas, over it at 650° C. for from 6 to 24 hours.[76] Alternatively,[77] reactivation of the catalyst is effected by passing a mixture of oxygen, nitrogen and carbon dioxide, or air and steam, over the heated catalyst for several hours.

A catalyst for the reaction of gaseous hydrocarbons, of higher molecular weight than methane, with steam at 400° to 1000° C. can be prepared, according to Hüttner and Wietzel,[78] by making a paste of a mixture containing at least one metal (or its oxide, hydroxide or carbonate) of the iron group together with a difficultly reducible oxide of a metal of Groups II to VI of the periodic system and a hydraulic binding agent. The paste is allowed to set before use. In the treatment of such gaseous hydrocarbons with steam at 400° to 1000° C., it is said to be advantageous [79] to use more than one layer of the catalyst, each succeeding layer having a higher activity, and being maintained at a lower temperature than the preceding one. Thus, if the first layer consists of a metal of the iron group made into an aqueous paste with a hydraulic binding agent, the next layer may consist of a similar group metal, activated, however, by the addition of a non-reducible oxide of a metal of Groups II to VI.

Williams [80] conducted a mixture of steam and gaseous hydrocarbons, such as methane, through a series of reaction vessels containing a number of superimposed trays on which the catalyst is placed. The temperature for the reaction is maintained by admitting small quantities of air to the free spaces just above each tray so that only a small part of the mixture is converted into hydrogen and carbon monoxide at every stage of the treatment. Overheating and undesirable side reactions are thus avoided.

Another proposed catalyst consists of nickel, cobalt, or iron mixed with aluminum compounds containing oxygen and at least one of the following elements: silicon, hydrogen, carbon, boron, phosphorus and sulphur (for example, kaolin), together with magnesium or an alkaline earth oxide.[81] The addition of phosphorus pentoxide to the nickel oxide-aluminum oxide catalysts has been recommended.[82]

Schulz and Eisenstecken [83] used catalysts of iron, cobalt, nickel, chromium, aluminum, manganese, copper, vanadium, tungsten, or their alloys with each other and effected the reaction of hydrocarbon gases with steam at 1000° C. in a channel of carborundum. The heat necessary for reaction is generated by induced high-frequency electric current. The catalyst or conveniently shaped metallic masses are placed in the reaction space to receive the electrical energy.

Other catalysts which have been suggested for the reaction of hydrocarbons and steam are the oxides of zirconium, aluminum, thorium and titanium.[84] The temperature is maintained above 900° C. when these are used.

APPLICATION OF THE STEAM REACTION IN THE "REFORMING" OF GASEOUS HYDROCARBONS

An important new application of the hydrocarbon-steam reaction is in the reforming of hydrocarbon gases, such as propane and butane, to yield gas mixtures having heating values and specific gravities similar to those of natural and coal-carbonization gases. By treating butane, for example, with steam in the presence of a catalyst, combustible gases can be obtained with calorific values ranging from 260 to 1800 B.t.u. depending upon the steam:hydrocarbon ratio, the temperature, and time of contact with the catalyst. On account of its great flexibility, such a reforming process is of value in supplying a gas useful to supplement natural gas supplies during periods of peak load. Oberfell and Guyer[85] gave the analyses in Table 71 of various gases made from butane by this steam-reforming process which show its utility for duplicating the qualities of other commercial gaseous fuels. The process is said to be applicable to low-boiling petroleum hydrocarbons.

FORMATION OF HYDROCYANIC ACID BY THE REACTIONS OF HYDROCARBONS WITH NITROGEN, AMMONIA, AND OXIDES OF NITROGEN

The production of hydrocyanic acid and cyanides from paraffin hydrocarbons, particularly from methane, has attracted much attention. The processes for making hydrocyanic acid from hydrocarbons vary. Mixtures of hydrocarbons (or carbon monoxide) with nitrogen or air, with ammonia and with the oxides of nitrogen have been suggested.

In this connection it may be well to mention briefly one early general method which has been used for the production of cyanides.[86] Desfosses[87] in 1828 observed the formation of sodium cyanide in small quantities on passing atmospheric nitrogen through a highly heated mixture of carbon and sodium carbonate. During the early part of the nineteenth century processes for producing cyanides from coal and air in the presence of alkalies and catalysts were developed.[88] The reaction represented by the equation:

$$Na_2CO_3 + 4C + N_2 \longrightarrow 2NaCN + 3CO - 138{,}500 \text{ cals.}$$

requires a temperature of the order of 1400° C. in the absence of catalysts.[89] Bucher[90] later proposed briquetting the mixture of sodium carbonate and coke with a catalyst consisting of metallic iron. Under these conditions nitrogen is readily absorbed at 920° to 950° C., yielding briquettes containing 26 to 30 per cent of sodium cyanide. According to Thompson,[91] a pure form of carbon such as produced by the thermal decomposition of hydrocarbons (lampblack or petroleum coke) or of carbon monoxide is superior to coke from coal for this purpose.

These processes in which coal or coke is the source of carbon were followed by others in which the carbon was supplied by hydrocarbons or oxides of carbon. This allowed the production of hydrocyanic acid entirely in the gaseous phase. Other gaseous nitrogen compounds such as ammonia and oxides of nitrogen were also substituted for the nitrogen. A large number of such procedures has been described since about 1840. Only those of more recent date in which hydrocarbons are used will be mentioned.

REACTION OF HYDROCARBONS WITH NITROGEN

The direct reaction of hydrocarbons with nitrogen to form hydrocyanic acid according to the equation, $2CH_4 + N_2 \rightarrow 2HCN + 3H_2$, requires very high temperatures for appreciable yields, because of the highly endothermic nature of the change. This reaction was observed by Berthelot[92] as taking place in the electric arc. Bone and Jerdan,[93] by the prolonged action of an electric discharge on methane mixed with traces of nitrogen, obtained a gas containing 0.8 per cent of hydrocyanic acid. The formation of hydrocyanic acid from nitrogen and hydrocarbons in an electric arc has also been discussed by Moscicki,[94] Koenig and Hubbuch[95] and Küster.[96]

The formation of alkaline cyanides and ammonia was observed by Fogarty[97] on conducting nitrogen and alkalies into a retort in which acetylene and other hydrocarbon vapors are being cracked. The hydrocarbon vapors are passed into the retort together with a stream of finely powdered alkali or alkaline earth.. In another process Fogarty[98] used producer gas. Colin[99] described a method of making cyanides and ammonia by passing air and fuel gas under pressure into a furnace. A volatile hydrocarbon is then introduced into the flame. The hydro-

cyanic acid thus produced is absorbed from the ascending current of incandescent gases by introducing a stream of finely powdered alkali or alkaline earth.

Gow[100] proposed mixing natural gas (containing 95 per cent of methane) with nitrogen or air and conducting the mixture through an electric arc. Best results were obtained with a spluttering arc.

By introducing a mixture of superheated nitrogen and a liquid hydrocarbon or acetylene into a fused mixture of sodium and potassium hydroxide at 300° C., Blackmore[101] obtained cyanides.

Sinding-Larsen[102] passed a mixture of nitrogen and the vapors of hydrocarbons over heated aluminum or silicon and obtained the nitrides of these metals together with volatile products containing ammonia and hydrocyanic acid.

Moscicki and Jablczynski[103] proposed to manufacture hydrocyanic acid by repeatedly heating a gas mixture containing nitrogen, hydrogen and a hydrocarbon at high temperatures, followed by cooling. The excess hydrogen is removed from time to time. The heating was effected in an electric furnace having a revolving high-tension flame, the temperature reaching 2500° to 3500° C.

Lipinski[104] synthesized hydrocyanic acid by conducting a mixture of oil gas and nitrogen over an extended flaming arc. After removing the resulting hydrogen cyanide the remaining mixture was recirculated with a fresh charge. A mixture giving satisfactory yields consists of 10 per cent hydrogen, 20 per cent methane, and 70 per cent nitrogen, according to Malisoff and Egloff.[105] A large excess of nitrogen is necessary to prevent the separation of free carbon. To produce long steady arcs and to catalyze the reaction, conducting vapors of metals or metallic compounds, such as copper or iron or their salts, can be introduced into the zone of electrical discharge.[106]

A process for making hydrocyanic acid from nitrogen, hydrogen and hydrocarbons under a pressure of about 1.6 atmospheres in an electric furnace containing a voltage arc was described by Liebknecht.[107] He produced 50 grams of hydrocyanic acid per kilowatt-hour of electricity from a mixture of 5.3 per cent carbon monoxide, 8.3 per cent methane, 33.7 per cent hydrogen, and 42.7 per cent nitrogen.

For the preparation of hydrocyanic acid, Muthmann and Schaidhauf[108] used an apparatus[109] consisting of a 1500 cc. glass retort with four side tubes, two of which carried electrodes and two served as inlet and outlet. An excess pressure of about 40 cm. of mercury was maintained in the apparatus and the power source was an alternating current of 50 cycles at 93 volts and a maximum of 43 amperes. The electrodes consisted of silver, gold and platinum screwed into cooled copper rods. The reaction between methane and nitrogen by this method gave hydrocyanic acid, equivalent in amount to the methane present, and hydrogen.

Hydrocyanic acid can be made, according to Helfenstein,[110] by introducing equal volumes of acetylene and nitrogen through a hollow vertical electrode into a molten slag bath on which there is a layer of animal charcoal.

Starke and Starke[111] described an apparatus in which cyanides are produced by passing a mixture of methane and nitrogen or air above 600° C. over a catalyst. The catalyst is formed by calcining a mixture of magnesium oxide, potassium carbonate, metallic iron, and acetic acid.

By injecting ammonia into heated natural gas or other hydrocarbon, Poindexter[112] obtained hydrocyanic acid. The natural gas, kerosene vapor or other hydrocarbon material may be mixed first with ammonia and then introduced into an externally heated zone.[113] The heated zone can be a glazed fireclay tube through which the gases are passed at such a rate that they are exposed for about one second to a temperature of 1200° C.[114]

According to the I. G. Farbenindustrie A.-G., the production of acetylene from hydrocarbons and hydrocyanic acid from mixtures of nitrogen and hydrocarbons in the electric arc can be combined. Thus,[115] in the treatment of gas mixtures containing hydrocarbons and nitrogen, a furnace is used having a central electrode and an annular or tubular electrode through which the gases are passed. An insulating mantle is arranged between the electrodes to allow for adjustment of the length of the arc to that most favorable to the reaction. Acetylene and hydrocyanic acid may be obtained by the action of the discharge on residual gases from synthetic ammonia or other hydrogenation plants, carbon monoxide being preferably removed first by catalytic reduction to methane.[116] The gases entering the arc are preheated by gases leaving it.

The simultaneous production of acetylene and hydrocyanic acid from methane and nitrogen by subjecting the gaseous mixture to an electric discharge has been mentioned by Küster.[117] With a load of 1.6 kilowatts and a gas mixture containing 15 to 25 per cent methane under a pressure of 10 to 15 mm., the resulting gas was found to contain about 10 per cent hydrocyanic acid.

Bagley[118] produced hydrocyanic acid by bringing nitrogen into contact with a bath of hydrocarbon oil under the surface of which an electric arc is maintained.

Ammonia together with hydrocyanic acid is produced when a mixture of gaseous hydrocarbons, nitrogen, and hydrogen is passed under pressures of from 1 to 350 atmospheres over alkaline earth cyanamides at temperatures varying from 200° C. to 1000° C. An example of such a process[119] is the passage of coke-oven gas, containing principally methane, nitrogen and hydrogen, over calcium cyanamide at 750° C.

REACTIONS OF HYDROCARBONS WITH AMMONIA

It has long been known[120] that by passing ammonia over heated carbon, hydrocyanic acid is formed according to the equation

$$NH_3 + C \longrightarrow HCN + H_2$$

In the presence of an excess of ammonia the hydrocyanic acid appears, of course, in the form of its ammonium salt. The reaction is an endothermic one and requires high temperatures for appreciable yields. Badger[121] investigated the equilibrium at a temperature of 800° Absolute (527° C.). The values of the equilibrium constant

$$K = \frac{p_{H_2} \times p_{HCN}}{p_{NH_3}}$$

at 800° Absolute averaged 5.8×10^{-6}. From existing data the heat content of hydrocyanic acid was calculated to be 30,500 calories at 18° C. and 30,400 calories at 800° Absolute and the free energy as 28,400 calories at 800° Absolute.

Hutton and Smith[122] showed that hydrocyanic acid is also formed when a mixture of hydrogen and nitrogen is heated at 1700° C. in the presence of carbon. Von Wartenburg[123] studied the equilibrium existing in this reaction.[124]

In a similar way ammonia and various hydrocarbons can react to form hydrocyanic acid and hydrogen. The reaction of methane may be represented by the equation:

$$CH_4 + NH_3 \longrightarrow HCN + 3H_2$$

Here again we are dealing with an endothermic reaction, so that high temperatures are necessary to obtain appreciable yields. In purely thermal processes, moreover, it is probably necessary to employ high temperatures in conjunction with short heating periods (exactly as in the case of the production of acetylene from methane by pyrolysis).

The formation of hydrocyanic acid by the reaction of ammonia with methane, ethylene, and acetylene at temperatures above 700° C. in the presence of contact materials has been systematically investigated by Bredig, Kortüm, Elöd, Müller, and Demme.[125] With rising reaction temperatures, the yields of hydrocyanic acid were found to increase to a maximum and thereafter decline. The reaction between ethylene and ammonia is actively catalyzed by a mixture of quartz and clay or by pure clay granules, and the highest yields of hydrocyanic acid are obtained by using equimolecular quantities of reactants. In the reaction between acetylene and ammonia, the yield of hydrocyanic acid at any one temperature was found to be independent of the contact time within the limits studied. Since methane was found to yield hydrocyanic acid only at temperatures which favored the formation of acetylene from this hydrocarbon, it was thought probable that the production of hydrocyanic acid from methane (and from ethylene) and ammonia proceeds through the intermediate formation of acetylene.

Peters and Küster[126] described the formation of hydrocyanic acid from mix-

tures of ammonia and methane by passing them at high gas velocities under diminished pressure through a high-voltage electric discharge. With gas mixtures containing 15 per cent, or less, of either ammonia or methane, a quantitative conversion of the smaller constituent into hydrocyanic acid could be effected. With more powerful discharges the excess methane was partly converted into acetylene and the excess ammonia was decomposed into its elements.

The processes proposed for the production of hydrocyanic acid from gaseous hydrocarbons and ammonia usually involve either heating to high temperatures with catalysts or exposure of the gaseous reactants to an electric discharge.

For example, Lance and de Bourgade[127] proposed to use a mixture of 80 liters of ammonia gas, 2000 liters of gaseous hydrocarbons (acetylene, ethylene or methane) with 200 liters of nitrogen at a red heat in order to obtain hydrocyanic acid. The use of nitrogen or a mixture of nitrogen and hydrogen as diluent gases is said to minimize carbon deposition during the reaction between ammonia and methane at temperatures of 1150° C. or higher at high space velocities.[128]

Beindl[129] suggested the reaction of a volatile nitrogen compound with liquid or gaseous hydrocarbons in the presence of contact materials such as copper or the oxides of iron. According to Beindl, passing a mixture of ammonia and acetylene over a copper catalyst at 480° C. results in the formation of hydrocyanic acid. Similar processes involving the production of hydrocyanic acid or cyanides from ammonia and hydrocarbons have been advanced by Woltereck[130] and de Lambilly.[131]

A gaseous mixture containing ammonia, oxygen and hydrocarbons (aliphatic or aromatic) is passed at a temperature of 700° to 1200° C. over an oxidation catalyst (iridium, platinum, rhodium, palladium, osmium, gold or silver, and the oxides or phosphates of the rare earths) to yield hydrocyanic acid on cooling. The gaseous product may be passed over alkali or alkaline earth metal oxides or hydroxides to form cyanides or cyanamides.[132]

Wheeler[133] reported a method for making hydrocyanic acid in which hydrocarbons (methane or coal gas) are heated to at least 800° C. before or after admixture with nitrogen or ammonia and the hot gaseous mixture is subjected to an arc or spark discharge. Better yields are obtained with an excess of nitrogen or ammonia. The gases used in this process should be free from oxygen.

REACTION OF CARBON MONOXIDE WITH AMMONIA

Kuhlmann[134] observed the formation of hydrocyanic acid when carbon monoxide was passed with ammonia over heated spongy platinum. Considerable interest has been displayed in the production of hydrocyanic acid by this apparently simple reaction of carbon monoxide and ammonia.[135] Thus Liebknecht passed a mixture of carbon monoxide and ammonia over a catalyst composed of a porous non-acid charcoal maintained at 400° to 800° C.[136] Frank and Caro[137] used a mixture of carbon monoxide and ammonia at ordinary or increased pressures. These gases are led over cyanides of the alkaline earths at 700° to 800° C., or over other compounds (such as the oxides, carbonates and others) which can be converted into cyanamides by the action of hydrocyanic acid or of the ammonia-carbon monoxide mixture. The process is carried out in the absence of activated charcoal and of metals catalyzing decomposition. Decomposition may, however, be prevented by the addition of poisoning substances such, for example, as sulphides.

Mittasch and Michael[138] used aluminum oxide as a catalyst. Another procedure is conducting a mixture of carbon monoxide containing 10 to 12 per cent of ammonia over catalysts composed of iron, cobalt, or nickel carbide.[139] The catalyst may also contain molybdenum, tungsten, cerium, titanium, or copper, in the free or combined state.[140] The carbides are made by melting the metals with finely divided carbon. The reaction to form HCN is carried out at a temperature below 600° C. (for example, 450° C.) so that the ammonia is appreciably converted. Internal or external heating may be employed. The hydrocyanic acid is removed either by condensation as ammonium cyanide or by absorption in caustic alkali solution, the residual gases being returned to the process.

To obtain cyanides Wittek[141] treated alkali hydroxides or carbonates in the presence of carbon with ammonia and carbon dioxide mixed with hydrocarbons at temperatures of 400° to 800° C. and at atmospheric or increased pressures. The process is said to be improved by a number of factors: for example, the presence of halides or cyanates; the use of catalysts such as copper, manganese or activated carbon; and the regulation of the water content of the furnace gases.

REACTION OF HYDROCARBONS WITH OXIDES OF NITROGEN

Kuhlmann[142] observed the formation of hydrogen cyanide on treating methane with nitric oxide in the presence of heated spongy platinum. This reaction has apparently not been as thoroughly investigated as that of carbon, carbon monoxide, or hydrocarbons with nitrogen or ammonia. Huntington,[143] however, used this reaction in a process for the production of hydrocyanic acid in which acetylene was mixed with nitric oxide and ignited in a cylinder with an electric spark. The hydrocyanic acid was absorbed in alkali.

Elöd and Nedelmann,[144] examining the action of nitric oxide on methane, ethylene and acetylene, arrived at the following conclusions:

> (1) Hydrocyanic acid is produced by the action of nitric oxide on the above-mentioned hydrocarbons at high temperatures. Under similar conditions the yield of hydrocyanic acid is greater from acetylene than from ethylene, and at the same time the quantity of polymerized substances and of formaldehyde is larger. The reaction temperature required by methane is 300° C. higher than for the other hydrocarbons for similar yields of hydrocyanic acid.
>
> (2) The reaction between nitric oxide and ethylene is catalyzed by various materials, of which the best is a mixture of equal parts of quartz and alumina. Addition of steam to the reaction mixture decreases the yield of hydrocyanic acid and increases the production of ammonia. The addition of hydrogen favors the formation of hydrocyanic acid.
>
> (3) The production of hydrocyanic acid increases greatly with rising temperature and is large at 1000° C. and over. With rising temperatures the ammonia production rises to a maximum and then declines. A large number of experiments conducted with nitrous oxide and ethylene at 900° C. showed that above this temperature pronounced polymerization and decomposition of the ethylene occurs.

According to Elöd and Nedelmann, the first stage in the process is the reduction of the nitric oxide to ammonia. Part of the ammonia then reacts with the hydrocarbon to form hydrocyanic acid (probably through the intermediary of unsaturated residues such as $:CH_2$ and $\vdots CH$), and the other part undergoes thermal dissociation to yield hydrogen and nitrogen. They saw very little probability of a reaction of ammonia directly with methane or solid carbon. The production of carbon monoxide may be accounted for by the reaction of ethylene with the water vapor formed in the reduction of nitric oxide. From these considerations it would appear that the process capable of giving best results would be the one starting with or favoring the initial formation of ethylene and ammonia.[145] Later results[146] have substantiated this, although the formation of acetylene seems a necessary condition for the production of hydrogen cyanide. Hydrocyanic acid is probably formed thus:[147]

$$2CO + NH_3 \longrightarrow HCN + CO_2 + H_2$$
$$CO_2 + H_2 \longrightarrow CO + H_2O$$

and by minor reactions involving the formation and decomposition of formaldehyde.

Chapter 11

Direct Hydration of Olefins to Alcohols

The conversion of olefins to alcohols is normally effected by first combining the olefin with relatively concentrated sulphuric acid and subsequently hydrolyzing the alkylsulphuric acid initially formed. The same end may also be attained by using other acids in a more or less concentrated form (e.g., hydrochloric acid or hydrobromic acid) and hydrolyzing the resulting alkyl esters as before. It may be noted, however, that the conversion of olefins into alcohols merely involves the addition of the elements of water to the olefin according to the general scheme

$$C_nH_{2n} + H_2O \longrightarrow C_2H_{2n+1}OH$$

In this chapter the formation of monohydroxy alcohols by direct hydration is considered, and the subject of polyhydroxy alcohols (particularly glycols) is discussed in Chapter 22.

Direct hydration of higher olefins is known to take place with considerable ease under the influence of various chemical reagents, notably dilute mineral acids, but the direct hydration of the lower members of the series has been found to be considerably more difficult.[1] Thus, for example, the transformation of isobutylene into trimethylcarbinol can be accomplished, according to Butlerow,[2] in the cold in the presence of sulphuric acid of moderate dilution. Butlerow and Goriainow[3] found that amylene and heptylene, as well as isobutylene, can be hydrated to the corresponding alcohols at room temperature by means of 10 per cent nitric acid or 50 per cent sulphuric acid but on heating to 100° C. polymerization becomes the predominating reaction. Later, Miklaschewsky[4] observed that isobutylene and some of the amylenes and hexylenes can be hydrated by means of 5 to 10 per cent aqueous solutions of formic, acetic, or oxalic acids with no appreciable polymerization. Incidentally, a very interesting case of the hydration of a double bond has been reported by Solonina,[5] who obtained propylene glycol by refluxing allyl alcohol with 10 per cent by weight of hydrochloric acid. Michael and Brunel[6] carried out some experiments on the reaction of isobutylene with various concentrations of hydriodic acid and found that free alcohol and isobutylene iodide were formed in proportions depending upon the concentration of the hydriodic acid. When 60 per cent hydriodic acid was used the product consisted almost entirely of the iodide but with lower concentrations the products contained an increasing proportion of free alcohol. In the reaction of trimethylethylene with hydrobromic acid it was noted that acid stronger than

---

[1] The hydration of olefins to alcohol might be designated as *aquolysis*, though strictly speaking this term is applied when water vapor is employed as a diluent at temperatures and pressures above the critical values (see Ellis, "Hydrogenation of Organic Substances," D. Van Nostrand Co., New York, **1930**, 585).

[6] *Amer. Chem. J.*, 1912, **48**, 269.

9.66 normal yielded the bromide exclusively, while acid strengths lower than 5.54 normal produced only the alcohol. With acids of intermediate concentration, mixtures of the bromide and alcohol were obtained. Michael and Brunel concluded that in the hydration of these olefins by hydriodic or hydrobromic acids, the iodide or bromide was the intermediate compound which was subsequently hydrolyzed to the alcohol.

Brooks and Humphrey,[7] in the course of their well-known work on the action of sulphuric acid on olefins, came to the conclusion that practically complete hydration of some of the olefins can occur even with relatively dilute acids, as in the commercial process for the manufacture of terpineol. Similar results have been obtained with the amylenes and halogen acids.[8] Many examples of the hydration of double bonds to give alcohols are known in the paramenthane series, e.g., the hydration of sabinene by cold dilute sulphuric acid to yield terpineol-4. Of interest is the hydration of allene and dimethylallene to acetone and methyl isopropyl ketone by the distillation with steam of a solution of these gases in concentrated sulphuric acid.

Some of the processes in which the higher olefins are hydrated to alcohols under the influence of dilute mineral acids undoubtedly involve the intermediate formation of an ester which subsequently undergoes hydrolysis to an alcohol with liberation of the acid. In this way the hydrating acid perhaps acts as a catalyst. The lower olefins, which are very much more resistant to this method of hydration, usually require comparatively concentrated acids to effect absorption under ordinary conditions. Consequently the esters are usually the main products of the process and it is impossible to obtain alcohols exclusively.

Various procedures have been advanced in which the lower gaseous olefins, particularly ethylene, are heated under high pressure with dilute aqueous solutions of mineral acids or certain metallic salts at temperatures above 200° C., but the yields of alcohol obtained thereby have been very small. The general reaction

$$C_nH_{2n} + H_2O \rightleftharpoons C_nH_{2n+1}OH$$

is an equilibrium process since dehydration of alcohols yields olefins. There are also certain side reactions involving the formation of ethers. By the application of the third law of thermodynamics to this equilibrium process, Francis[9] deduced the following expression for the free energy of the synthesis of alcohols from olefins:

$$\Delta F = -5320 + 815n + 17.2T - 0.5nT,$$

in which n is the number of carbon atoms and T is the absolute temperature.

In the case of the lower olefins, this expression is positive for ordinary temperatures so that the tendency for alcohol formation from ethylene and water is small, i.e., at ordinary temperatures only relatively small amounts of alcohol would be in equilibrium with ethylene and water. Moreover, as the temperature is increased the expression for the free energy of formation becomes greater positively so that a rise in temperature should be unfavorable for alcohol production. On account of lack of reliable data it is almost impossible to apply the Nernst approximation formula to these equilibria. Since hydration takes place with a decrease in the number of molecules, increase of pressure should favor the formation of alcohols. Moreover, as may be inferred from the foregoing, low temperatures should favor the alcohol yields. However, as the reaction velocity is low at low temperatures, efficient catalysts are necessary for hydration under optimum conditions.

[7] *J.A.C.S.*, 1918, **40**, 822.

[8] Butlerow, *Ann.*, 1877, **189**, 51; Wischnegradsky, *ibid.*, 1878, **190**, 351; Eltekow, *Ber.*, 1877, **10**, 707; Konowalow, *Ber.*, 1880, **13**, 2395.

[9] *Ind. Eng. Chem.*, 1928, **20**, 283; *Amer. Pet. Inst. Bull.*, 1930, III, 93.

Loveless and Wright[9a] calculated the relative values of the velocity and equilibrium constants over the temperature range of 0° to 500° C. They point out that the absolute values of these constants can be determined only if the integration constants can be evaluated. This requires a knowledge of the equilibrium proportions of ethylene, water and alcohol under one known set of conditions and the time required for the reaction to proceed to a measured extent. Thus far such data are not available. The free energy changes associated with the hydration of ethylene have been derived from the free energy data obtained by Francis,[9b] who gives the following equations:

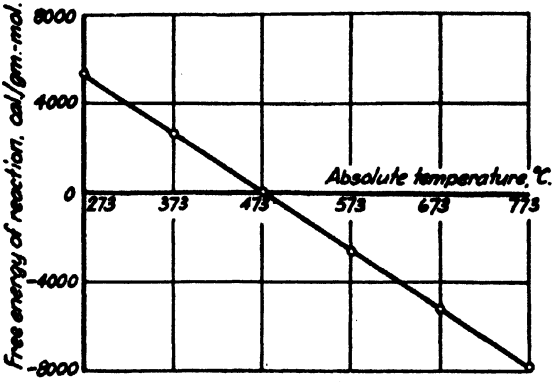
$$A_{C_2H_4} = 17{,}680 + 11.1T \ln T + 0.0055T^2 - 65T$$

$$A_{H_2O} = -57{,}410 + 0.94T \ln T + 0.00165T^2 - 0.00000037T^3 + 3.92T$$

$$A_{C_2H_5OH} = -50{,}520 + 20.33T \ln T - 0.0131T^2 - 85T$$

in which A is the change in free energy (calories per gram molecule) of formation of corresponding substances. For the hydration of ethylene in the vapor phase, the change in free energy is expressed by

$$\begin{aligned} A_{\text{Reaction}} &= A_{C_2H_4} + A_{H_2O} - A_{C_2H_5OH} \\ &= 10{,}790 - 8.29T \ln T + 23.92T + 0.00925T^2 - 0.00000037T^3 \end{aligned}$$



Courtesy Journal of the Royal Technical College (Glasgow).

FIG. 20.—Change in Free Energy of Reaction of Ethylene and Water with Temperature. (Loveless and Wright.)

This change in free energy plotted against the temperature over the range 0° to 500° C. (Fig. 20) gives a straight line which can be represented by the equation

$$A_{\text{Reaction}} = 12{,}600 - 26.3T$$

The rate of formation of alcohol can be expressed by the equation

$$\frac{dx}{dt} = k_1 (a - x)(b - x) - k_2 x$$

[9a] *J. Roy. Tech. Coll. (Glasgow)*, 1933, 3, 65.
[9b] *Loc. cit.*

in which k_1 and k_2 are the velocity constants for the forward and reverse reactions, respectively, a and b are the initial concentrations of ethylene and water, respectively, and x is the concentration of alcohol after time t.

The variation of the constant k with the temperature is given by the equation

$$\frac{d \ln k_1}{dT} = \frac{A}{RT^2} = \frac{1}{R}\left(\frac{12{,}600}{T^2} - \frac{26.3}{T}\right)$$

which on integrating becomes

$$\ln k_1 = -\frac{1}{R}\left(\frac{12{,}600}{T} + 26.3 \ln T\right) + C_1$$

The values of $(\ln k_1 - C_1)$ over the temperature range are shown in Figure 21. This curve indicates that the optimum temperature for investigating the effect of pressure on the reacting system is 200° C.

Variation of the equilibrium constant with the temperature is shown by the equation

$$\frac{d \ln K}{dT} = -\frac{U}{RT^2}$$

in which U is the heat of reaction.

$$\begin{aligned} U &= A - T\frac{dA}{dT} \\ &= 12{,}600 - 26.3T + T26.3 \\ &= 12{,}600 \text{ calories per gram molecule} \end{aligned}$$

Substituting this value of U in the above equation

$$\frac{d \ln K}{dT} = -\frac{12{,}600}{RT^2}$$

which on integrating becomes

$$\ln K = \frac{12{,}600}{RT} + C_2$$

The calculated values of $(\ln K - C_2)$ over the same temperature range as that for the variation in velocity constant are shown in Figure 22.

Catalysts capable of being used for hydration processes include dilute mineral acids which possibly are active by virtue of the presence of (hydrated) hydrogen ions, assumed to be the catalytic agents in many hydrolytic reactions. More concentrated acids possess esterifying action and the resulting alkyl esters are simultaneously hydrolyzed to a greater or less extent depending upon the acid concentration. A number of difficultly reducible metallic oxides exert a profound catalytic effect on both hydrating and dehydrating reactions. Among these may be mentioned alumina, thoria, and zirconia. Phosphoric acid (and its anhydride) has long been known as a valuable agent for the dehydration of alcohols so that its activity in the hydration of olefins is to be expected. Certain metallic phosphates, notably cadmium metaphosphate and cerium metaphosphate, have been mentioned as powerful catalysts for the hydration of ethylene. The mode of action of these catalysts is still uncertain but the observation of Weber and Walton[10] that the catalytic activity of phosphoric acid in the dehydration of ethyl alcohol to ethylene at 210° to 250° C. is much increased by the addition of 1.5 to 2 per cent of copper oxide, copper sulphate, silver sulphate, or aluminum sulphate, suggests that the metals function as promoters in conjunction with phosphoric acid. In a similar way Sabatier found that the dehydrating action of sulphuric acid on ethyl alcohol is accelerated by the addition of silver salts but Joshua, Stanley and Dymock[11] have employed sulphuric acid and silver sulphate on pumice as a catalyst for the vapor phase hydration of olefins. It appears therefore that the dehydrating and hydrating activity of both phosphoric and sulphuric acids is enhanced by the presence of certain of their metallic salts. In the case where a gaseous olefin is being forced to react with an aqueous liquid, any influence tending to increase the olefin concentration in the liquid phase is calculated to accelerate the reaction. For this reason certain metallic salts (e.g., silver, cuprous, and mercury salts) having a strong affinity for olefins have been proposed as catalysts for the hydration of olefins in the presence of liquid water.

FIG. 22.—Variation of Reaction Constant of Ethylene and Water with Temperature. (Loveless and Wright.)

ETHYLENE

Ethyl alcohol can be dehydrated to yield ethylene and water by warming with sulphuric or phosphoric acid, or, in the vapor phase, by heating in the presence of difficultly reducible oxide catalysts, such as alumina. The reverse reaction, or the hydration of ethylene to ethyl alcohol, was probably first shown by Cotelle.[12] The method used by him consisted in passing a mixture of steam and ethylene through a reaction tower countercurrent to a hot stream of dilute (10 to 12 per cent) sulphuric acid. Hot acid solution was withdrawn from the base of the tower, while alcohol and water vapors, together with unreacted ethylene, escaped at the top.

Another demonstration of the reversibility of the reaction

$$C_2H_5OH \rightleftharpoons C_2H_4 + H_2O$$

---

[11] British Patent 370,136, 1931; assigned to The Distillers Co., Ltd.; *Brit. Chem. Abs.* **B**, 1932, 716.
[12] U. S. Patent 41,685, Feb. 23, 1861.

was advanced by Wibaut and Diekmann,[13] who found when a mixture of ethylene and steam was passed over alumina, or aluminum sulphate, at 300° to 400° C., the reaction products contained 0.2 to 0.4 per cent of acetaldehyde. That this was not due to the oxidation of the ethylene was shown by passing a mixture of air and ethylene over the same catalysts at 360° C., when no acetaldehyde was formed, and hence the first step must have been the addition of water to the double bond, forming alcohol. In studying the action of an acid catalyst, the same investigators passed ethylene at ordinary pressure countercurrent to a descending stream of 65 per cent sulphuric acid at 156°-160° C. When passed at a rate of about 1 liter of ethylene per hour, approximately 5 per cent conversion to alcohol took place. Practically no conversion resulted with 55 per cent sulphuric acid.

When the general equation of Francis is applied to the equilibrium $C_2H_4 + H_2O \rightleftharpoons C_2H_5OH$, the free energy of the alcohol synthesis reduces to

$$\Delta F = -3690 + 16.2T.$$

This expression is positive even at ordinary temperatures and increases (positively) with rising temperature. This indicates that the tendency for the reaction yielding alcohol to proceed would be small even at ordinary temperatures and would decrease at higher temperatures. The best conditions for the synthesis of alcohol from ethylene and water would therefore be:

(1) High pressures;
(2) Low temperatures consistent with sufficient velocity of reaction; and
(3) Highly efficient catalysts to bring about equilibrium quickly.

So far no catalyst has been discovered capable of inducing the reaction with sufficient speed at ordinary temperatures.

Klever and Glaser[14] recorded an important series of experiments on the hydration of ethylene. At atmospheric pressure hydration in the presence of mineral acids at 100° C. is very slow, but the reaction velocity increases considerably at higher pressures and temperatures, although the absolute effect is very slight. After 17 hours at 150° C. and 190 atmospheres pressure, one mole of water had hydrated only 0.00011 mole of ethylene, while at 200° C. and 100 atmospheres 0.0008 mole of ethylene was hydrated per mole of water. Under the latter conditions the effect is very favorably influenced by the presence of sulphuric acid in a concentration of over 0.17 per cent and of hydrochloric acid over 0.005 per cent. At a concentration of 1.93 per cent HCl, the catalytic effect is so marked (at 200° C. and 100 atmospheres) that more than one mole of ethylene is hydrated per mole of HCl. The intermediate product in the reaction was considered to be ethyl chloride, which was subsequently hydrolyzed to ethyl alcohol.

Swann, Snow and Keyes[15] have reported some results obtained by the hydration of ethylene and propylene under pressures of 600 to 800 lbs. per square inch at temperatures up to 200° C. in the presence of dilute mineral acids and solutions of metallic salts. Practically no hydration occurred in the presence of water alone. Table 72 gives these investigators' results.

It will be seen from Table 72 that the results indicate that halogen acids and salts do actually function as catalysts, but that the equilibrium concentration of alcohol is very small, as predicted by theoretical considerations. Swann and his

It will be seen that increasing the concentrations of the halogen acids favors the formation of the alkyl halide without greatly increasing the alcohol yields. With concentrated halogen acids, large quantities of the alkyl halide are formed.

Johannsen and Gross[16] advocated the direct hydration of ethylene by heating under pressure in the presence of water containing a small proportion of mineral acid. Temperatures of 200° C., pressures of not less than 20 atmospheres, and 4.3 per cent hydrochloric acid are recommended.

---

[16] U. S. Patent 1,607,459, Nov. 16, 1926; *Chem. Abs.*, 1927, 21, 249. Also Röchlingsche Eisen- und Stahlwerke A.-G., British Patent 238,900, 1925; *J.S.C.I.*, 1925, 901B.

Smith and Bridger[17] described a process for producing ethyl alcohol from ethylene and water by hydration in the liquid phase under high pressure at temperatures of 200° to 300° C. in the presence of an inorganic salt having an affinity for ethylene (silver nitrate, cuprous chloride, and mercuric chloride) dissolved or suspended in water. A conversion of 10 per cent of the ethylene was obtained with a saturated aqueous solution of mercuric chloride in an autoclave protected by an internal coating of "Vitreosil."

Slade[18] proposed to hydrate ethylene to ethyl alcohol by passing it with excess of steam at 400° to 500° C. and 25 to 200 atmospheres over a dehydrating catalyst such as thoria, or phosphoric acid on pumice. The reaction is effected in the vapor phase and at a high space velocity (10,000 to 50,000 liters of gas at N.T.P. per hour per liter of catalyst). Heat interchange between the outgoing and incoming gases assists the reaction. The ethylene may be diluted with other gases and the process may be conducted in a continuous manner.

The vapor phase hydration of the lower olefins, including ethylene and propylene, is accomplished by passing them with steam at ordinary or increased pressures over certain catalysts at temperatures above 100° C. (usually about 150° to 300° C.). The catalysts proposed include finely divided metals of the platinum group, gold, silver, copper, iron, cobalt, nickel, chromium, tantalum, vanadium, tungsten, molybdenum or manganese, or their salts or other compounds.[19] These may be suspended on inert carriers or supports. This process is exemplified by the hydration of ethylene with steam over a catalyst of copper phosphate on pumice at 150° C. and atmospheric pressure. Hydration of ethylene or propylene takes place under similar conditions in the presence of catalysts consisting of copper oxide and tungstic oxide, of ferric oxide and tungstic oxide, or of finely divided platinum on pumice. In some instances appreciable proportions of the dehydrogenation products of alcohols (aldehydes and ketones) are obtained.

Direct hydration of ethylene with steam in the vapor phase may yield diethyl ether as the main product, small amounts of ethyl alcohol being simultaneously formed.[20] Conversion is effected by passing a gaseous mixture of steam and ethylene, with the latter in excess, under high pressure over various contact catalysts at temperatures below 300° C. and at moderate rates of gas flow (100 to 1000 liters of gas per hour per liter of catalyst). The catalysts may consist of non-volatile inorganic or organic acids or acid anhydrides (e.g., sulphuric acid, sulphonic acids, or better, phosphoric acid or phosphorus pentoxide) distributed on inert carriers. Phosphates of the rare earth metals, such as cerium metaphosphate, are particularly specified and the activity of the above catalysts is said to be improved by the addition of other substances, as, for example, zinc oxide or anhydrous zinc chloride. The amount of water vapor should not exceed 25 per cent by volume of the ethylene as otherwise marked formation of alcohol takes place. The following example illustrates this method: 24 liters of ethylene and 3 liters of water vapor (calculated under atmospheric pressure and at 20° C.) per hour are passed at 200° C. under a pressure of 125 atmospheres over 100 cc.

(apparent volume) of active carbon impregnated with a mixture of 11.25 grams of phosphorus pentoxide and 11.25 grams of phosphoric acid. About 7 cc. of ethyl ether and 0.5 cc. of ethyl alcohol are obtained per hour in one passage, corresponding to a 14 per cent yield of ether calculated on the ethylene employed.

Several processes developed by Joshua, Stanley, and Dymock deal with the direct vapor phase hydration of olefins to alcohols and particularly of ethylene to ethyl alcohol. Thus it is proposed[21] to hydrate ethylene to ethyl alcohol by passing it with steam at atmospheric or higher pressures and at temperatures of 140° to 200° C. over a contact mass of porous inert material (pumice) impregnated with about 60 per cent by weight of sulphuric acid, the concentration of the acid being maintained from about 60 per cent to 85 per cent by adjustment of the steam partial pressure. It is reported that by passing a mixture of 2 parts of ethylene and 1 part of steam at a gas rate of 180 liters per hour (calculated at normal temperature and pressure) over 3.6 liters (apparent volume) of the above catalysts at 170° C. and at a pressure of 15 atmospheres, a condensate was obtained containing 7.15 per cent of ethyl alcohol, representing a conversion of ethylene of 1.39 per cent.

Joshua, Stanley, and Dymock[22] further described the hydration of olefins to alcohols, with particular reference to ethylene, in the vapor phase in the presence of a catalyst of pumice (or other porous material) impregnated with about 60 per cent by weight of sulphuric acid together with a promoter, such as silver sulphate, known to accelerate the absorption of ethylene in concentrated sulphuric acid. For example, by passing a gaseous mixture of 1 part of ethylene and 1.5 parts of steam at a gas rate of 6.25 liters of the mixture per hour over a catalyst of 150 cc. (apparent volume) of pumice impregnated with 60 per cent by weight of sulphuric acid and 5 per cent by weight of silver sulphate at 145° C. and atmospheric pressure, a conversion of ethylene into ethyl alcohol of 1.6 per cent was obtained. The same investigators suggested[23] the hydration of olefins, particularly ethylene, to alcohols in the vapor phase by passing them with steam, most effectively under pressure, over certain acid sulphates (acid sodium sulphate or acid potassium sulphate) at temperatures not exceeding 350° C., particularly between 100° and 250° C.

Horsley[24] described a process for the direct vapor phase hydration of ethylene to ethyl alcohol under pressure in the presence of certain phosphate catalysts, notably a catalyst obtained by heating together cadmium oxide and phosphorus pentoxide in the molecular ratio of about 1:0.9. If the molecular proportion of phosphorus pentoxide falls below 0.725 the activity of the catalyst declines. Other catalysts (of somewhat lower activities than the cadmium phosphate) described by Horsley are the phosphates of beryllium, zinc, aluminum, tin, or lead. The reaction may be carried out either in the liquid or the vapor phase and at ordinary or increased pressure, the reaction temperature being preferably 100° to 300° C. To hydrate in the liquid phase, the olefin is compressed to, e.g., 100 atmospheres and passed through an aqueous solution of the catalyst salt to which has been added sufficient phosphoric acid to suppress hydrolysis. When operating in the vapor phase, it is best to employ a large excess of olefin relative to water vapor and the gaseous products are cooled to separate an aqueous alcohol solu-

tion, the surplus ethylene being recirculated. This procedure is exemplified in the following: A catalyst was prepared by heating one mole of cadmium oxide and 1.5 moles of phosphoric acid in aqueous solution, the mixture being evaporated to dryness at a temperature below 130° C. and the product made into small pellets. A mixture of ethylene and steam under a total pressure of 100 atmospheres, the partial pressures of steam and ethylene being 30 and 70 atmospheres respectively, was passed over this catalyst at 290° C. with a contact time of about 1 minute. The products were said to consist of 243 grams of ethyl alcohol and 1.0 gram of ethyl ether per hour, together with 6.9 grams per hour of oily polymerization products. The yield of alcohol on the ethylene consumed was 95 per cent with a conversion per single passage of 3.36 per cent of the theoretical.

Later, Horsley[25] proposed to remove propylene from crude ethylene, which is to be used in the above hydration process, by polymerizing the propylene in the presence of the cadmium phosphate catalyst under conditions which leave the ethylene unchanged. It is probable therefore that the use of such catalysts in the hydration of the homologues of ethylene would be accompanied by the occurrence of polymerization reactions.

Phosphate catalysts, particularly those of uranium, iron and cobalt are employed by Joshua, Stanley and Dymock.[26] The proportion of phosphoric acid in the catalyst is in excess of that required for the orthophosphate of the metal used, but should not exceed 95 per cent of the composition of the finished material. Reaction between ethylene and water in the presence of these catalysts is carried out at temperatures of 100° to 300° C. (best above 150° C.) and at pressures up to 250 atmospheres. Some results obtained at atmospheric pressure with a number of iron catalysts (made by decomposing ferrous oxalate with phosphoric acid and drying at 200° C.) are given in Table 74. The percentage conversion of ethylene to ethyl alcohol was determined under fixed conditions, i.e., a gas rate of 3.12 liters of ethylene per hour per 100 cc. (apparent volume) of catalyst, an ethylene-steam ratio of 1 : 1.5 (by volume), and a catalyst temperature of 200° C., and also under variable conditions.

TABLE 74.—*Hydration of Ethylene with Iron Catalysts.*

Catalyst	Temperature ° C.	Pressure in Atmospheres	$C_2H_4:H_2O$ Molar Ratio	Liters of Ethylene per Hour per 100 cc. of Catalyst	Percentage Conversion of Ethylene to Ethyl Alcohol
$FeO \cdot 2H_3PO_4$	200	1	1:1.5	3.12	0.41
$FeO \cdot 2.5H_3PO_4$	200	1	1:1.5	3.12	0.69
$FeO \cdot 2.7H_3PO_4$	200	1	1:1.5	3.12	0.56
$FeO \cdot 3H_3PO_4$	200	1	1:1.5	3.12	0.40
$FeO \cdot 2.5H_3PO_4$	270	20	4:1	400	0.83
$FeO \cdot 2.5H_3PO_4$	280	40	7:1	1260	0.67

Catalysts prepared in a similar manner from cobaltous or uranyl oxalate were not as effective as the iron phosphates.

Manganese or copper phosphates (containing excess phosphoric acid) are recommended also.[27] For example, when ethylene and steam (in the molar ratio of 5.4: 1) are conducted over a copper phosphate catalyst (made from one mole of copper oxide and 2 moles of phosphoric acid) at 300° C., under a pressure of 40 atmospheres and at a gas rate of 1200 liters of ethylene per 100 cc. (apparent volume) of catalyst per hour, 22.1 grams of ethyl alcohol as a 14.5 per cent aqueous condensate is obtained. This corresponds to a 1.12 per cent conversion of ethylene.

A study of the vapor phase hydration of ethylene at 360° to 380° C. at pressures of 70 to 135 atmospheres in the presence of alumina and tungstic oxide was conducted by Sanders and Dodge.[27a] Twenty-eight catalysts were prepared and tested by determinations of their efficiency in dehydrating ethyl alcohol to ethylene. Alumina and tungstic oxide (in one) were used in the hydration experiments, of which several results are given in Table 75.

[a] Liters of off-gas (at standard conditions) per hour per liter of catalyst.

Bent[28] has described the hydration of ethylene and its homologues by heating under high pressures in the presence of dilute aqueous solutions, or suspensions, of certain sulphates of heavy metals, zinc sulphate being specifically mentioned. The best results are obtained by bringing the olefin in contact in a continuous manner with an aqueous solution of zinc sulphate containing 8 to 25 per cent of $ZnSO_4.7H_2O$ (at 25° C.) at a temperature of 275° to 325° C. and a pressure from 175 to 250 atmospheres. Water is continually added to replace that carried forward as steam and alcohol. Thus, ethylene is treated at a rate of 1 liter per minute[29] with 300 grams of an aqueous solution of zinc sulphate solution (containing 25 per cent of the hydrated salt) maintained at a temperature of 300° C. and under a pressure of 210 atmospheres. About 20 per cent of the ethylene is converted into ethyl alcohol. The excess ethylene, after separation of the alcohol vapors, is recirculated.

Boron phosphate, free from excess boric and phosphoric acids, has been suggested as a catalyst for the hydration of olefins in either the gaseous or liquid phase.[30] This catalyst is prepared by evaporating to dryness a mixture of boric acid (62 grams) and an aqueous solution of phosphoric acid (100 grams). The resultant boron phosphate is freed of excess phosphoric acid by heating to 400° C. in a current of steam until the condensate gives no acid reaction with bromthymol blue. Hydration is carried out under pressure and at temperatures of 150° to 300° C. Passage of a mixture of 70 volumes of ethylene and 30 volumes of steam over this catalyst, under a total pressure of 100 atmospheres, at 290° C., and at a space velocity of 6000 reciprocal hours, yielded 155 grams of alcohol per hour per liter (apparent volume) of catalyst. No oil was produced under these conditions.

[28] British Patent 378,764, 1931; assigned to Bataafsche Petroleum Maatschappij; *Brit. Chem. Abs.* B, 1932, 1071. See also French Patent 729,765, 1931; *Chem. Abs.*, 1933, 27, 305.

[29] It is not specified whether this gas volume is measured at N.T.P. (the usual practice) or under the working pressure. On the former basis, the alcohol output per hour per liter of catalyst would be about 82 grams.

[30] Horsley, British Patent 378,865, 1931; assigned to Imperial Chemical Industries, Ltd.; *Brit. Chem. Abs.* B, 1932, 1071. See also Imperial Chemical Industries, Ltd., French Patent 734,989, 1932; *Chem. Abs.*, 1933, 27, 992.

The use of boron phosphate containing at least 10 per cent excess phosphoric acid over that required for the orthophosphate is advocated by Joshua, Stanley and Dymock.[31] Such a material is made by evaporating to dryness a mixture of one mole of boric acid anhydride and 2.2 moles of phosphoric acid, and heating the residue to 200° C. Passage of ethylene and steam (molar ratio of 4:1) under 20 atmospheres pressure, at a temperature of 270° C., and a gas velocity of 400 liters per hour per 100 cc. (apparent volume) of catalyst, yielded 3.70 grams of alcohol (per hour) as a 5.6 per cent aqueous condensate. This was equivalent to 0.44 per cent conversion of ethylene to ethyl alcohol.

Brown and Odell[32] described the hydration of olefin hydrocarbons to alcohols and ethers by passage with steam under pressure over catalysts (e.g., the oxides of aluminum, thorium, titanium, tungsten and chromium) at temperatures of 100° to 600° C. The relative proportions of alcohols and ethers formed are controlled by varying the temperature and the ratio of steam to olefin in the reacting gases. Generally, high temperatures and an excess of steam favor alcohol formation. In hydrating ethylene homologues somewhat lower temperatures are employed than with ethylene.

Dreyfus[33] effected direct hydration of olefins, particularly of ethylene to ethyl alcohol, by passage with steam (10 to 20 moles of olefin to 1 mole of steam) under pressure through heated liquid catalysts consisting of aqueous sulphuric, phosphoric, or sulphonic acids. When hydrating ethylene, the concentration of the sulphuric acid should be maintained at about 55 to 65 per cent, while concentrations of phosphoric acid of at least 85 per cent are necessary. As an illustration of this process, a mixture of ethylene and steam (in the molar proportions of 18 to 1) is conducted under a pressure of 50 atmospheres through aqueous sulphuric acid of about 75 per cent concentration at 165° C. and at a space velocity of 8000 liters per hour (calculated at N.T.P.) per liter of catalyst. The acid concentration falls to a steady value of 60 to 63 per cent. When using phosphoric acid, a higher temperature range (200° to 300° C.) is employed.

Dreyfus[34] also proposed to hydrate olefins in the presence of mineral acids of 60 to 90 per cent concentration (sulphuric and phosphoric acids) under pressure and at temperatures of 100° to 350° C. To these acids is added 2 to 40 per cent of the sulphuric or phosphoric esters of glycols, polyvalent alcohols (glycerol) and of higher fatty acids. Substances which aid the absorption of olefins in acids, such as lead or silver sulphate, may also be present in the catalyst liquid. A mixture of ethylene and propylene is hydrated, for example, in the presence of 70 per cent sulphuric acid containing 15 per cent of aromatic sulphostearic acids and about 5 per cent of hydroxystearylsulphuric acid, all maintained at 180° C.

A modification[35] of the above processes involves the use of dilute solutions of mineral acids. Concentrations of acid varying from 2 to 10 per cent are

[31] British Patent 396,724, 1933; assigned to The Distillers Co., Ltd.

[32] U. S. Patents 1,873,536 and 1,873,538, Aug. 23, 1932; *Chem. Abs.*, 1932, 26, 5962, 5963. In this latter patent saturated hydrocarbons are used as starting materials, being cracked to olefins.

[33] British Patent 389,133, 1931; *Brit. Chem. Abs.* B, 1933, 457; also French Patent 741,068, 1932; *Chem. Abs.* 1933, 27, 2691.

[34] French Patent 744,164, 1933; *Chem. Abs.*, 1933, 27, 3942.

[35] Dreyfus, French Patent 744,482, 1933; *Chem. Abs.*, 1933, 27, 3942.

recommended, though concentrations as high as 50 per cent may be employed. Thus, a mixture of 3 volumes of ethylene and 2 volumes of steam, preheated to 150° C., is led through 10 per cent sulphuric acid at 200° C. under a pressure of 25 atmospheres. The time of contact is about 30 seconds.

Dreyfus[36] also proposed to effect the hydration of olefins, particularly ethylene, in the presence of certain acid salts having an affinity for water. Such salts include bisulphates, pyrosulphates, particularly those of the alkali metals, calcium chloride, zinc chloride and magnesium chloride. A mixture of steam with at least an equal molar proportion of the olefin is passed under pressures up to 25 atmospheres over these catalysts at 150° to 350° C.

The alkali hydroxides and other basic substances have been suggested as catalysts for direct hydration, especially at temperatures of 150° to 250° C. and under pressures of 50 atmospheres or higher.[37] Calcium or magnesium oxide may be employed as catalysts, either alone or in conjunction with alkali hydroxides. The passage of equal volumes of ethylene and steam through a 50 per cent potassium hydroxide solution at 150° C. under 20 atmospheres pressure and also the use of pumice impregnated with sodium hydroxide to catalyze a mixture of one volume of ethylene and two volumes of steam at 200° C. under 30 atmospheres pressure are examples of this process.

Other catalysts which have been suggested are liquid phosphoric acid[38] and the molten chlorides of metals at least as electropositive as nickel, e.g., calcium, zinc or magnesium chloride.[39]

Another procedure, which apparently combines both direct esterification and hydrolysis of the esters formed, consists in conducting (under pressure) steam, olefin and the vapors of aliphatic acids (e.g., acetic or trichloroacetic acid) over catalysts, such as zinc chloride, at temperatures of 150° to 600° C. The proportion of acid vapors should be small as compared with the olefin and steam present, so that only a small amount of esters is produced.[40]

A two-stage process is described by Dreyfus,[41] in which olefins are absorbed (under 50 to 100 atmospheres pressure and at temperature of 250° to 300° C.) in aqueous solutions of orthophosphoric acid, or of weaker acids. The products are subsequently hydrolyzed with water or steam. The concentration of the acid employed varies with the individual olefin, being about 80 per cent for ethylene, 75 per cent for propylene, and 60 per cent for higher olefins.

COMPARISON OF AVAILABLE DATA ON HYDRATION OF ETHYLENE

In the absence of any published systematic study of the relative efficiencies of various catalysts for the hydration of ethylene, the somewhat meager information available furnishes the only basis for such comparison. Unfortunately, however, this information is not always sufficient for an adequate assessment of the value of a process. From the viewpoint of the industrial application of the hydration reaction, the most rational basis of comparison would be the hourly output of alcohol per unit volume (apparent) of catalyst at a definite pressure and temperature. Table 76 contains the data available in this connection.

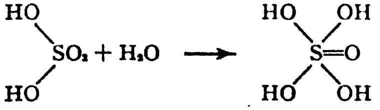
PROPYLENE

Little work has been done on the direct hydration of propylene to isopropyl alcohol or on the direct hydration of butene-1 and butene-2. As pointed out previously the hydration of isobutylene, hexenes, and certain heptenes appears to take place very readily under the influence of moderately dilute mineral acids. The hydration of olefins by dilute mineral acids probably runs parallel, to some extent at any rate, with the tendency to form alkyl esters with more concentrated acids. Brooks and Humphrey[41a] concluded from their work that the tendency of aliphatic olefins to form alkylsulphuric esters and alcohols appeared to be at a maximum with the amylenes and hexylenes. It was also noted that when the simple olefins such as the amylenes, hexenes, or heptenes are carefully treated with 85 per cent sulphuric acid at a temperature not exceeding 15° C. and the resulting clear, amber-colored acid solution slowly poured into iced water, there is immediately precipitated a pale yellow oil containing as its chief constituent the free (secondary or tertiary) alcohol corresponding to the original hydrocarbon. To account for the fact that free alcohol was not present before dilution while the rates of hydrolysis of the alkylsulphuric esters concerned were far too low to admit of the degree of hydrolysis observed, Brooks and Humphrey assumed that the actual intermediate products were readily hydrolyzable alkyl esters of orthosulphuric acid, the latter being formed by the union of water and sulphuric acid according to the scheme:



[41a] *J.A.C.S.*, 1918, 40, 822. *Cf.* Michael and Brunel, *Amer. Chem. J.*, 1909, 41, 118.

Swann, Snow, and Keyes[41b] studied the direct hydration of propylene under 600 to 800 lbs. per square inch pressure at 135° C. in the presence of dilute hydrochloric acid and aqueous solutions of silver nitrate. Their results are recorded in Table 77.

TABLE 77.—*Hydration of Propylene.*

Expt.	Pressure Lbs./sq. in.	Temp. ° C.	Duration Hours	Catalyst	Conc. of Alcohol Wt. %
19	600	135	1	5% HCl	0.44
20	600	135	1	$AgNO_3$	0.22
21	800	135	1	5% HCl	0.63
22	800	135	1	$AgNO_3$	0.32
23	800	135	1	$AgNO_3$	0.29

It will be seen from the above figures that though the extent of hydration of propylene is several times greater than that of ethylene under similar conditions, the effect is still very minute. The application of the general formula of Francis for the free energy of formation of alcohols from olefins and water to propylene leads to the following expression:

$$\Delta F = -2875 + 15.7T.$$

This is no more promising from the point of view of the synthesis of isopropyl alcohol from propylene than is that for the production of ethyl alcohol from ethylene. On the other hand, it is stated that propylene and higher olefins may be catalytically hydrated to secondary and tertiary alcohols in such a way that propylene and its higher homologues may be removed from mixtures with ethylene, which is itself largely unchanged under the conditions employed.[41c] This would indicate that propylene and its homologues are much less resistant to catalytic hydration than is ethylene. In this process, propylene and its immediate higher homologues are allowed to react with a dilute acid, or aqueous salt solution having an acid reaction, in the presence of a catalyst at 100° to 250° C. (preferably 150° to 220° C.) and at a partial pressure of the olefin gas not less than 10 atmospheres. Catalysts specified are bismuth chloride, bismuth oxychloride, cuprous chloride, copper sulphate, copper phosphate, copper toluene-p-sulphonate, copper naphthalene disulphonate, silver sulphate, and silver naphthalene disulphonate. As dilute acids, hydrochloric, sulphuric, or phosphoric acids, or organic sulphonic acids such as toluene-p-sulphonic and naphthalene disulphonic acids, may be employed.

McKee and Burke[41d] recommended a procedure for the manufacture of higher (secondary and tertiary) alcohols from ethylene homologues by vapor phase hydration, using a mixture of steam and the olefin at temperatures of 350° to 450° C. and pressure of 25 to 200 atmospheres in the presence of dehydrating oxide catalysts, such as alumina, thoria, or zirconia.

In a process[42] which has been previously discussed, the direct vapor phase hydration of propylene is proposed in the presence of catalysts consisting of certain finely divided metals of the platinum group, or gold, silver, copper, iron, cobalt, nickel, chromium, tantalum, vanadium, tungsten, molybdenum, or manganese, or salts or compounds thereof, at temperatures above 100° C. (best at 150° to 300° C.) and even at atmospheric pressure. A mixture of copper oxide and tungstic acid is mentioned as particularly applicable for the hydration of propylene. A mixture of propylene and water vapor is conducted at a velocity of 6.7 cc. per hour (per cubic centimeter of apparent catalyst volume) over a catalyst, made by depositing 15 grams of cupric oxide and 15 grams of tungsten trioxide on 150 grams of active carbon. The aqueous condensate obtained at a reaction temperature of 300° C. is reported to contain alcoholic bodies.

[42] Bataafsche Petroleum Maatschappij, British Patent 335,551, 1930; *Brit. Chem. Abs.* **B**, 1931, 12.

Bent[43] has suggested the direct hydration of propylene to isopropyl alcohol by heating under high pressure in the presence of aqueous solutions of sulphates. Propylene is introduced at a rate of about 7 liters per minute into a pressure vessel containing 650 grams of an aqueous solution of zinc sulphate (8 per cent $ZnSO_4.7H_2O$ at 25° C.) at a temperature of 286° C. and a total pressure of 210 atmospheres. Isopropyl alcohol, water and unused propylene are continuously withdrawn from the top of the container and water is fed in to maintain the concentration of the aqueous solution.

Boron phosphate is a catalyst for the vapor phase hydration of propylene.[44] On passing a mixture of equal volumes of steam and propylene at a space velocity of 1000 reciprocal hours over this catalyst at 200° C. at atmospheric pressure, a condensate was obtained which contained 1 per cent by weight of isopropyl alcohol, corresponding to a yield of 98-99 per cent of the propylene reacting. This represents a conversion of propylene per passage of about 0.3 per cent at a time of contact of 3.6 seconds. About the same degree of conversion is secured with ethylene under similar conditions of steam to olefin ratio, temperature, pressure, and space velocity in the presence of cadmium (acid) phosphate.[45]

In the process of Suida,[46] the higher homologues of ethylene are said to be converted into a mixture of the corresponding alcohols and their esters by causing such olefins to react with dilute aliphatic acids in the presence of not more than 5 per cent of a strong mineral acid under pressure at temperatures above 100° C. For example, propylene is absorbed in a 15 per cent aqueous acetic acid solution containing 3 per cent of concentrated sulphuric acid at 150° C. under 20 atmospheres pressure to yield a product consisting of isopropyl alcohol and isopropyl acetate in the proportion of 8:1.

ISOBUTYLENE

As previously indicated, isobutylene in conjunction with certain other branched chain olefins can be slowly hydrated even in the presence of 5 to 10 per cent aqueous solutions of weak organic acids without appreciable polymerization. The hydration of these hydrocarbons in the presence of such feeble catalysts is too slow, however, for commercial purposes. Owing to the pronounced tendency of isobutylene to polymerize in the presence of strong acids, even at low tempera-

tures, attempts to hydrate this olefin and similar reactive olefins in the presence of the known active hydrating catalysts would undoubtedly lead to the formation of relatively large proportions of polymerized substances. Francis[47] gave the figures in Table 78 for the equilibrium constants of the reaction between isobutylene, water, and tertiary butyl alcohol at two temperatures.

The figures in Table 78 show that the tendency for isobutylene to react with water to form tertiary butyl alcohol falls off very rapidly with rising temperature, although at the lower temperature (80° C.) quite high conversions of isobutylene into the corresponding alcohol are theoretically possible.

BUTENE-2

A study of the hydration of butene-2 to butanol-2 in the vapor phase under high pressure has been contributed by Marek and Flege.[48] The catalysts employed were cuprous chloride, phosphoric acid, copper phosphate and thoria at temperatures of 427° to 538° C. The pressures were 3000 and 5000 pounds per square inch (211 and 352 kg. per sq. cm., respectively). Under these conditions the hydration reaction was accompanied by polymerization, to avoid which a large excess of steam over butene was employed. The yield of polymerized products was reduced by increasing the steam-butene ratio and increased by the use of higher pressures and temperatures. All the catalysts were effective in speeding up hydration reactions but exerted little effect on polymerization. This is shown by the data in Table 79, all of which refer to experiments at a pressure of 3000 pounds per square inch using a reaction mixture consisting of 50 moles of steam to 1 mole of butene.

products in the condensate. Under comparable conditions, the amount of olefin hydrated relative to that polymerized was greatest with the phosphoric acid catalyst. An increase in the time of contact from 65 to 364 seconds in the presence of phosphoric acid at 427° C. varied the percentage hydration of butene-2 to only a slight degree, indicating that equilibrium was approached under these conditions. At higher temperatures, however, an increase in the contact time resulted in diminished yields of hydrated products and an increase in polymerization.

The experiments in Table 81 on the influence of pressure in the presence of various catalysts, show that an increase of pressure from 3000 to 5000 pounds per square inch favored polymerization to a much greater extent than hydration.

Under conditions where polymerization was reduced to a negligible amount, the conversion of butene-2 into hydrated products was only about 3 to 6 per cent per passage even under such high pressures as 3000 pounds per square inch (210 atmospheres). Marek and Flege, however, employed much higher temperatures than are usually considered desirable and accordingly a large excess of steam over butene was necessary to suppress polymerization. By using more active catalysts at lower temperatures it should be possible to employ lower steam-olefin ratios without the occurrence of extensive polymerization. A further disadvantage of temperatures as high as 400° to 500° C. is that under such conditions the alcohols tend to become dehydrogenated, yielding ketones and their condensation products.[49] Accordingly purer alcohols would probably be obtained by conducting hydration at lower temperatures in the absence of catalysts capable of catalyzing dehydrogenation.

The hydration of butenes by heating with aqueous solutions, or suspensions, of the heavy metals sulphates, particularly zinc sulphate, has been suggested by Bent.[50] Temperatures of 200° to 375° C. and pressures not less than 100 atmospheres are recommended.

SUMMARY AND CONCLUSIONS

The general reaction

$$C_nH_{2n} + H_2O \rightleftharpoons C_nH_{2n+1}OH$$

is reversible and represents both the direct hydration of olefins to alcohols and the dehydration of alcohols to olefins. While some of the higher olefins, such as amylenes, hexenes or isobutylene, appear to be hydrated fairly readily by moderately dilute mineral acids, the simple gaseous olefins, ethylene and propylene, are much more resistant to direct hydration. The thermodynamic calculations indicate that comparatively low temperatures are necessary to obtain appreciable quantities of alcohols and that efficient catalysts and high pressures are required. Even at low temperatures the equilibria are well over to the olefin side of the equation, i.e., the equilibrium concentrations of alcohol are small.[50a]

From the calculated free energies of the formation of alcohols, up to and including hexanol, Frost[51] concluded that high pressures and temperatures of 227° to 427° C. favor the direct hydration of olefins.

In spite of these adverse considerations much work has been done with a view to perfecting processes for the alluring reaction of direct hydration of the lower olefins. It cannot be said, however, that these efforts have been crowned with anything in the nature of success. Doubtless the seeming simplicity of the reaction will continue to entice that type of investigator who possesses the confidence that success lies just around the corner.

On the other hand, from details given in the process[52] of the I. G. Farbenindustrie already noted, it appears that propylene is somewhat more amenable to the hydration process than is ethylene.

Very much more promising than the direct hydration of ethylene and propylene appears to be the use of acids of catalytic strength, i.e., of a strength exceeding that necessary for the direct hydration process but yielding, on combination with gaseous olefins under pressure, not only free alcohols but also alkyl esters of the mineral acid. Thus, for example, Swann, Snow and Keyes[53] in discussing the results obtained by heating ethylene under 800 lbs. per square inch pressure in the presence of halogen acids of higher ranges of concentration, state:

"Increasing the concentration of hydrobromic or hydriodic acids favors the formation of the alkyl halide without apparently increasing the alcohol formation. With the concentrated acid, large proportions of the alkyl halide are formed. Since the halides are so easily obtained in large quantities and since they may be rather easily hydrolyzed photochemically or catalytically, an indirect process (of making alcohol) may be developed involving the steps: formation of alkyl halide, hydrolysis of halide, and reconcentration of acid." It is difficult to see, however, in what way such a process will offer advantages over the sulphuric acid process, particularly as halogen acids are difficult to reconcentrate in bulk.

---

[49] The butanol-2 obtained by Marek and Flege showed an acetylation value corresponding to about 81.5 per cent butanol.

[53] *Loc. cit.*

Closely related is the proposal advanced by McElroy[54] to manufacture alcohols by passing a current of gaseous olefins (propylene especially) upwards in intimate contact with a downwardly moving current of hot dilute acid (of catalytic hydrating strength), removing alcohol vapors, water vapor and residual gas after such contact, removing concentrated acid liquor at the bottom, and subsequently returning the acid to the top of the tower after adding to it sufficient water to compensate for that used up in the hydration process. Such a process might be considered to occupy a position midway between the direct hydration process and the ordinary concentrated sulphuric acid process. The alkylsulphuric esters are hydrolyzed by dilution with water, the alcohols distilled off, and the acid reconcentrated to its original esterifying strength for further use.

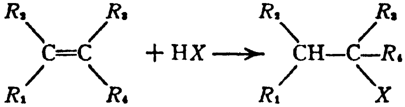
Chapter 12

Direct Esterification of Olefins with Mineral and Organic Acids

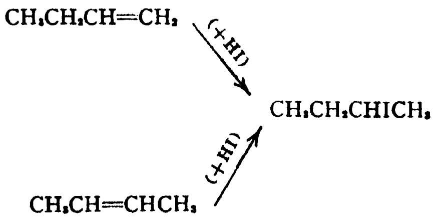
Many instances are known of the direct combination of olefins with mineral and other acids to yield esters of alcohols, and evidence of many more is being rapidly accumulated. The subject is of very great importance since the normal procedure for the manufacture of alcohols from olefins includes the union of these compounds with sulphuric acid to produce alkylsulphuric esters. Moreover the possibility of directly esterifying olefins to yield certain desirable esters of the corresponding alcohols opens up a wide and promising field of research.

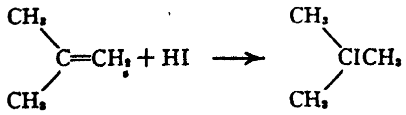
The reaction involved in the direct esterification of olefins may be expressed by the equation:



where R_1, R_2, R_3, and R_4 are aliphatic radicals or hydrogen, and X represents an acidic radical such as —Cl, or —SO_4H. Under the proper conditions, however, this reaction becomes a reversible one.

An important rule governing the addition of halogen acids to olefins is that proposed by Markownikov,[1] who stated that the halogen atom of the halogen acid tends to become united to the carbon atom which is combined with the least number of hydrogen atoms. Another way of stating this is that addition takes place in such a manner as to produce the maximum number of methyl groups in the molecule. Thus 1-butene and 2-butene add hydriodic acid with the production of the same secondary butyl iodide,[2] while isobutylene yields the tertiary iodide almost entirely.





---

[1] *Ann.*, 1870, 153, 256. Also, Butlerow, *Ann.*, 1868, 145, 274.

[2] Lieben and Rossi, *Ann.*, 1871, 158, 166.

However, Ipatiev and his collaborators[3] found that when the higher ethylenic hydrocarbons are treated with a solution of hydrogen bromide in glacial acetic acid the combination does not take place normally according to Markownikov's rule as there is also found a certain amount of abnormal products. For various olefins the proportion of these products formed is different and becomes less with the increasing difference between the amounts of hydrogen united with the carbon atoms on either side of the double linking. Thus with isobutylene, containing the grouping $>C=CH_2$, the proportion of abnormal product is 6 to 7 per cent; with trimethylethylene, having $>C=CH—$, 10 to 15 per cent and with isopropylethylene, possessing $—CH=CH_2$, 50 per cent.

The work of Ipatiev has been confirmed and enlarged to a certain extent by Delacre.[4] The latter found that crude 3.3-dimethyl-1-butene and hydrogen bromide gave the primary bromide instead of the expected secondary derivative. It was thought that the impurities associated with the crude hydrocarbon exerted the same action as acetic acid, the solvent employed by Ipatiev.

According to Brunel[5] the equilibrium

$$\text{isobutyl bromide} \rightleftharpoons \text{tertiary butyl bromide}$$

is established at 280° C. when the mixture contains about 90 per cent of the tertiary bromide. Thus the reaction of halogen acids with isobutylene at high temperatures yields principally the tertiary product, though at lower temperatures somewhat more of the isobutyl bromide is obtained.

ETHYLENE

The direct combination of ethylene and sulphuric acid to yield the ethyl esters of sulphuric acid has long been known. The preparation of ethyl and of isopropyl alcohols from ethylene and from propylene, respectively, by the formation of the corresponding alkylsulphuric acid and subsequent hydrolysis, was investigated by Berthelot.[6] The absorption of the olefins by the acid did not take place under practical optimum conditions, however, and the yields of alcohols were insignificant.

The ethylene is normally absorbed in about 96 per cent sulphuric acid at a temperature not greatly exceeding 100° C. Plant and Sidgwick[7] later showed that besides ethylsulphuric acid some diethyl sulphate, $(C_2H_5)_2SO_4$, was formed, but not until the concentration of ethylsulphuric acid had attained a high figure. Still later, Damiens[8] observed that the yield of diethyl sulphate was higher at low temperatures and with concentrated (100%) sulphuric acid. Maimeri[9] found that if the absorption of pure ethylene in 100 per cent sulphuric acid was conducted under pressure it then became very rapid and much diethyl sulphate was formed at ordinary temperatures. Thus at 3.5 atmospheres pressure of ethylene (using 100% acid) the yield of diethyl sulphate was 35 per cent and of ethylsulphuric acid 51 per cent, based on the sulphuric acid, while at 10 atmospheres pressure, the diethyl sulphate yield had increased to 62 per cent and the ethylsulphuric acid yield diminished to 30 per cent of the sulphuric acid. In general, however, when the absorption is conducted at atmospheric pressure, using 96 per cent sulphuric acid, very little diethyl sulphate is formed, the main product being ethylsulphuric acid.

A detailed account of the various factors influencing the direct combination of ethylene with sulphuric acid is unnecessary at this stage since it is discussed at length in Chapter 13. It is of interest to note, however, that certain derivatives of sulphuric acid combine with ethylene to yield ethyl esters, as for example benzenesulphonic acid. Chlorosulphonic acid, when mixed with an equal weight of sulphuric acid (100%), was shown by Traube and Justh[10] to absorb ethylene rapidly and quantitatively from coke-oven gas with the production of ethyl chlorosulphonate, ($ClSO_3C_2H_5$, b.p. 155° to 160° C. at 760 mm.), which on hydrolysis yielded a mixture of ethyl alcohol, ethyl chloride, and sulphuric and hydrochloric acids.

The absorption of ethylene by means of ortho-, pyro-, and metaphosphoric acids at 140° C. and 1 atmosphere pressure was investigated by Müller,[11] who reported that ethyl dihydrogenphosphate was formed with orthophosphoric acid, and possibly also with the pyrophosphoric acid. The rate of absorption decreased as the quantity of dissolved gas increased. However, at the end of 17 days, 100 grams of orthophosphoric acid had absorbed 1200 cc. of ethylene at 115° to 145° C. The presence of a small amount of cuprous oxide or silver sulphate greatly increased the absorptive power of the acids.

The direct combination of ethylene with gaseous hydrogen chloride was first attempted by Berthelot[12] but without success, although this investigator was able to effect the combination of ethylene with hydrobromic and hydriodic acids with the production of the corresponding ethyl halides. Berl and Bitter[13] later found that the direct union of ethylene with hydrogen chloride would proceed in the presence of aluminum chloride as catalyst at temperatures of 100° C. and above (most advantageously at 130° to 170° C.) without the formation of appreciable quantities of by-products. Owing to the slowness of the reaction, prolonged contact with the catalyst was necessary for good yields of ethyl chloride. Much information regarding this reaction has been furnished by the work of Wibaut and his collaborators,[14] who carried out a systematic examination of the effects of various catalysts on this reaction under atmospheric pressure and at various temperatures. Bismuth trichloride on asbestos was reported to be the best catalyst for this reaction, other catalysts of lower activity being ferric chloride, vanadium trichloride and aluminum chloride. At ordinary temperatures in the presence of the bismuth trichloride the reaction proceeds slowly, but at higher temperatures (e.g., 200° to 215° C.) the yield of ethyl chloride is 80 per cent, or more, of the ethylene used. With the same catalyst, good yields of ethyl chloride could be obtained from mixtures of ethylene and coal gas or water gas, even at ethylene concentrations as low as one or two per cent.

A point of interest in regard to the combination of ethylene with hydrogen chloride is the fact that the reaction is a reversible one since ethyl chloride can be made to yield ethylene and hydrogen chloride when passed over heated catalysts. Many other reactions of a similar type, for example, the combination of ethylene, propylene, and higher olefins with anhydrous halogen acids, are also reversible under certain conditions. In the case of the combination of ethylene with hydrogen chloride according to the reaction

$$C_2H_4 + HCl \rightleftharpoons C_2H_5Cl$$

the equilibrium is well over to the side of the ethyl chloride even at 200° C. but the amount of dissociation increases with rise in temperature. From a measurement of the equilibrium constants of this reaction at 114° and 124° C., which were found to be $K_{114} = 0.818 \times 10^{-8}$ and $K_{124} = 2.186 \times 10^{-8}$ where

$$K = \frac{p_{C_2H_4} \times p_{HCl}}{p_{C_2H_5Cl}}$$

Wibaut and Tidman have arrived at the value of 29.9 Cals. for the heat of reaction at constant pressure, which is in good agreement with Berthelot's thermal data.

The synthesis of ethyl chloride by the direct combination of ethylene with hydrogen chloride has attracted much attention probably largely from the point of view of the possible production of ethyl alcohol by the hydrolysis of the ethyl chloride formed. A number of interesting methods have been devised for carrying out such reactions. Thus, for example, Wibaut [15] prepared alkyl halides by passing a mixture of olefin and hydrogen chloride or bromide over a metal of the fifth group (e.g., a bismuth trihalide) at temperatures above 100° C. but not exceeding 250° C., the product being collected by absorption in activated charcoal. Higher temperatures are required when the olefin is diluted with other gases or air.

Suida [16] effected the combination of ethylene and hydrogen chloride, at atmospheric or increased pressure, in the presence of porous material impregnated with the liquid double compound of aluminum chloride and ethylene, $(C_4H_8AlCl_3)_x$, obtained by the passage of ethyl chloride over powdered aluminum chloride at 100° to 120° C. until it is completely converted into a dark brown liquid. On conducting a mixture of hydrogen chloride and ethylene over this catalyst at 90° C., a yield of 66 per cent is obtained. Suida [17] also described the direct combination of ethylene with hydrogen chloride at a pressure of 30 atmospheres and at temperatures below 50° C., conveniently at 10° C., in the presence of ferric chloride, aluminum chloride, or the molecular compounds of these with ethylene. As a modification of the above process, ethylene is combined with hydrogen chloride under 60 atmospheres pressure in the presence of an inert solvent, e.g., ethyl chloride itself, using aluminum chloride or its double compound with ethylene as a catalyst.[18] A similar combination of conditions has been suggested by Suida,[19] and the use of aluminum chloride to catalyze the combination of ethylene with hydrogen chloride has also been proposed by Webb.[20]

Acid-resistant adsorbents are recommended by Strange and Kane [21] as catalysts for the direct combination of low molecular weight olefins with hydrochloric or hydrobromic acid. The adsorbents mentioned are active carbon or activated charcoal, colloidal silica, or natural siliceous materials which have been dehydrated or extracted with acids, such as kieselguhr. The reaction takes place at temperatures below 120° C.

The direct combination of ethylene with hydrogen bromide apparently occurs much more readily than in the case of hydrogen chloride. Thus, Berthelot,[22] on heating ethylene with a saturated solution of hydrobromic acid at 100° C. in a sealed tube for 100 hours, obtained a large quantity of ethyl bromide. Ethylene and a solution of hydriodic acid were found to react somewhat more rapidly. Gustavson [23] observed that the direct combination of ethylene with gaseous hydrogen bromide took place in the presence of aluminum bromide at 0° C. with the production of ethyl bromide and also other products. At higher temperatures, however, the reaction product was a complex mixture in which hydrocarbons and complex double compounds of aluminum bromide were present. Wibaut, Diekmann and Rutgers [24] observed that an efficient catalyst for this reaction was bismuth tribromide dispersed on asbestos. These workers noted that, in the presence of bismuth tribromide, the addition of hydrogen bromide to ethylene proceeds even at 20° C., and at atmospheric pressure at a much greater rate than that of hydrogen chloride under similar circumstances.

A method, which apparently combines dehydration of the alcohol to the olefins and subsequent addition of the halogen hydride, was described by Carlisle.[25] This consists in passing the vapors of the alcohol together with the halogen hydride over an aluminum oxide catalyst maintained at a temperature of 150° to 300° C.

Maass, Wright, and Sivertz [26] observed that in a mixture of liquid ethylene and liquid hydrogen bromide (under pressure) no reaction occurs at 0° C., although a slow reaction proceeded in the case of a mixture of liquid propylene and liquid hydrogen bromide at —78° C. Later Swann, Snow and Keyes [27] showed that ethylene heated under fairly high pressure (about 800 pounds per square inch) to 150° C. with moderately concentrated aqueous solutions of halogen acids (hydrobromic and hydriodic acids) yielded considerable quantities of ethyl halides together with very small amounts of free alcohol. Thus on heating 150 cc. of 45 per cent hydriodic acid together with ethylene, under an ethylene pressure of 800 pounds per square inch, for 3 hours at 150° C., 24 grams of the ethyl halide were obtained.

The direct esterification of ethylene by means of organic acids is apparently very difficult to effect. In the presence of condensing agents, such as sulphuric acid, esterification does take place. For example, Traube and Justh [28] found that ethylene and chlorosulphonic reacted in the presence of sulphuric acid to form ethyl chlorosulphonate. Ellis [29] proposed to esterify olefins with organic acids by heating in the presence of sulphuric or phosphoric acids. The olefins may be used directly, or dissolved in an inert solvent, such as a petroleum distillate. Or the olefins may be first absorbed in sulphuric acid and then the salt of an organic acid added, such as calcium acetate.[30]

In producing esters by the reaction between calcium acetate and alkyl sulphates in the presence of an inert organic solvent, the addition of a hygroscopic solid material, such as plaster of Paris or sodium sulphate, facilitates the separation of the calcium sulphate from the reaction mixture.[31]

Alkyl esters may be obtained also by the action of an aqueous solution of hydrogen chloride (or bromide) on dialkyl sulphates or alkylsulphuric acids at temperatures above 100° C.[32] An alternate method consists in absorbing the olefin in sulphuric acid and causing the alkylsulphuric acid to react (by heating) with a carboxylic acid, e.g., acetic or benzoic acid. The addition of neutral sulphate or phosphate in quantity sufficient to bind the free sulphuric acid present and that formed during the reaction is necessary.[33]

PROPYLENE

Propylene is capable of combining with both mineral and organic acids much more readily than ethylene. Indeed it appears to be a general rule that the chemical reactivity of the olefin hydrocarbons increases with increasing molecular weight up to a certain maximum and then declines.

In comparing the additive powers of ethylene, propylene, n- and iso-butylene, trimethyl- and tetramethylethylene, and also di-isobutylene with various mineral acids, Brunel and Probeck[34] found that a maximum was obtained with isobutylene.

Although, as stated, the union of propylene with sulphuric acid takes place much more readily than in the case of ethylene, isopropylsulphuric acid, though formed in quantity under certain circumstances, is by no means the only product of the reaction. A number of side reactions take place and in order to obtain appreciable quantities of isopropyl alcohol it is necessary to adjust the conditions very carefully. Ellis[35] has shown that for the production of isopropyl alcohol the olefin should be dissolved in 87 per cent acid (d 1.8). Absorption can be continued until the density has fallen to 1.4, and during absorption the temperature of the acid should be maintained at 20° to 40° C. The gases may be absorbed directly by the acid, or in the presence of a diluent such as a petroleum distillate.

Any substance which is miscible with the olefins and unreactive with the acid is a satisfactory diluent. The mechanism by which this diluent prevents polymerization is probably as follows:

(1) The diluent molecules are right beside the reacting olefin molecules at the interface and therefore absorb the heat of reaction at the point where it is evolved, and thus lessen local overheating.

(2) If pure olefins react with acid, the instant some olefin molecules are absorbed by the acid absolutely fresh olefin molecules rush to the interface and there are capable of instant reaction with the further evolution of heat. When, however, a diluent is present, then, after the first instant of reaction during which only the surface layer of reactive olefin molecules in the hydrocarbon mixture react, the acid is left in contact with an insulating layer of inert hydrocarbon. The reaction therefore ceases, except as fresh reactive olefin molecules diffuse up to the acid surface through this insulating layer of hydrocarbons. These diffusion processes are notably slow, and the reaction rate is therefore retarded. This gives time for the heat evolved at the interface to dissipate itself and local overheating is again eliminated.

> (3) As far as the olefinic constituent of the mixture is concerned sulphation is a unimolecular reaction, and proportional to the olefin concentration at the interface. Polymerization, on the other hand, must from its very nature be proportional to the square of the olefin concentration at the interface, or perhaps even a higher power. Furthermore, it is the interfacial concentration alone that counts in this respect. Therefore dilution tremendously reduces the ratio of polymerization to sulphation and makes it possible to raise the temperature and thus avoid the cost of low-temperature refrigeration. At the same time, increasing the sulphation rate by increasing the temperature far more than compensates for the reduction in sulphation rate due to dilution. Thus the reaction is made commercially possible.

Liquid hydrocarbon diluents are employed by Ellis and by Mann and Williams.[36] If an easily volatile diluent starts to heat at the interface, vapor will be formed, and since vapor formation absorbs a large quantity of heat the interface will therefore be cooled. Furthermore, the vapor insulates the hydrocarbon liquid from the acid, thereby slowing the reaction and hence also the evolution of heat. This is also an important auxiliary factor in making the conditions of sulphation commercially effective.

After absorption is completed the acid layer is diluted with water, to bring about hydrolysis, and then distilled. Isopropyl alcohol is obtained in the distillate.

In their work Plant and Sidgwick[37] observed that, after acid of 97 per cent strength had absorbed 50 per cent by weight of propylene in 2 hours, a colorless oil separated. This oil, boiling from 55° to 155° C. at 30 mm., was considered by them to be a mixture of open-chain secondary alcohols, produced by the action of sulphuric acid on propylene polymers. Ormandy and Craven[38] later reported, however, that the oily products obtained by the action of 98 per cent sulphuric acid on propylene consist partly of paraffin hydrocarbons. Undoubtedly the action of sulphuric acid on propylene and the higher olefins, under certain circumstances, may lead to a complex mixture of products. Under other conditions, good yields of isopropylsulphuric acid, and then isopropyl alcohol, may be obtained.

The reaction of propylene with halogen acids has been studied by Maass, Wright and Sivertz,[39] who found that in a mixture of liquid propylene and liquid hydrogen bromide at —78° C. a slow reaction occurs resulting in the formation of isopropyl bromide and in addition another product of higher boiling point, probably a hexyl bromide. Liquid hydrogen chloride and liquid propylene reacted slowly at 20° C. forming besides isopropyl chloride an appreciable amount of a higher boiling substance, later[40] identified as a hexyl chloride (probably 2-chloro-4-methylpentane). The velocity of the reaction between propylene and hydrogen chloride in the liquid state increased with rise in temperature; above the critical temperature, however, the reaction velocity became almost zero.[41] It was found, moreover, that in a gaseous mixture of hydrogen chloride and propylene enclosed in a glass vessel (without catalysts) no reaction occurred at room temperature even when the experiment was continued for 400 days. Some work on the addition of propylene to gaseous hydrogen chloride and bromide has been carried out by Wibaut and his collaborators,[42] who have shown that in the presence of a bismuth chloride-asbestos catalyst hydrogen chloride reacts vigorously with propylene at room temperature, the product being 2-chloropropane (isopropyl chloride). At 80° to 90° C., in the presence of this catalyst, the yield of isopropyl chloride was 91 per cent based on the propylene used. Gaseous hydrogen bromide was found to react with propylene at 20° C. in the presence of pure asbestos, though bismuth tribromide dispersed on glass wool was the best catalyst. In the presence of the latter material, the combination of hydrogen bromide and propylene occurred readily at 20° C. (the temperature rising to 40° C. spontaneously) and the yield of 2-bromopropane was 93 per cent of the theoretical. Antimony tribromide also was observed to exert considerable catalytic influence on the reaction. Furthermore, after the methyl group in propylene is halogenated, the addition of a halogen acid yields 1,3-dihalogen propane, a reagent used in organic syntheses.

[42] *Loc. cit.*

The conversion of propylene into isopropyl chloride by direct combination with hydrogen chloride according to the reaction:

$$C_3H_6 + HCl \rightleftharpoons C_3H_7Cl$$

has been the basis for a number of processes, particularly those of Wibaut,[43] Curme,[44] and the T. Goldschmidt A.-G.[45] Curme proposed to make isopropyl chloride by allowing anhydrous propylene to react with hydrogen chloride under 15 atmospheres pressure, a solvent being added if desired. In the process of the T. Goldschmidt A.-G. propylene and its higher homologues may be converted into the corresponding alkyl chlorides preferentially, so that any admixed ethylene is not attacked, by passing these olefins together with hydrogen chloride over a contact mass of anhydrous iron chloride at ordinary temperatures.

Although the reaction between propylene and hydrogen bromide is generally assumed to give isopropyl bromide, nevertheless, the addition of modifying agents to the reacting substances makes it possible to obtain either n- or isopropyl bromide as the main product. In the presence of air or antioxidants (e.g., diphenylamine) isopropyl bromide is obtained almost exclusively, though the presence of peroxides (e.g., benzoyl peroxide), gives practically quantitative yields of n-propyl bromide.[46]

Not a great deal of work has been done on the direct combination of propylene with organic acids, although this reaction is capable of being achieved under certain conditions with the production of esters of isopropyl alcohol. Thus, Ellis [47] has proposed the esterification of olefins by organic acids in the presence of sulphuric acid, or by absorbing them in sulphuric acid and then adding the salt of an organic acid. The production of ethyl acetate was accomplished by Oehme [48] by treating a solution of ethylene in concentrated sulphuric acid with glacial acetic acid. Also, Woolcock [49] reported that good yields of isopropyl acetate may be obtained by absorbing propylene in a mixture of glacial acetic and concentrated sulphuric acids. On treating a mixture of equal volumes of 99.5 per cent sulphuric acid and glacial acetic acid with gaseous propylene at 40° C. and at atmospheric pressure until no more propylene was absorbed, the yield of isopropyl acetate was 27 per cent of the propylene absorbed while 53 per cent was recovered as isopropyl alcohol (through the intermediate formation of isopropylsulphuric acid), representing a total yield of 80 per cent, based on the amount of propylene absorbed.

Suida[50] recommended that the addition of organic acids to olefins, in the presence of sulphuric acid as a catalyst, be effected at 180° C. and under pressure of 20 to 50 atmospheres.

Direct combination of olefins and aliphatic carboxylic acids takes place in the presence of the chlorides, bromides, phosphates or sulphates of heavy metals, as well as sulphuric or phosphoric acid or their acid salts.[51] The reaction is carried out at any desired pressure and at a temperature above the boiling point of the ester (at the pressure employed), thus allowing its removal from the reaction zone as a vapor.

BUTENES

The tendency of the olefin hydrocarbons having four or more carbon atoms per molecule to combine with acids with the formation of the esters of the corresponding secondary and tertiary alcohols is relatively great in comparison with ethylene and propylene. Of the three isomeric butylenes, isobutylene is much more reactive toward acids and forms the esters of tertiary butanol with considerable ease. The other two butylenes both give rise to esters of the secondary alcohol, namely $CH_3CH_2CHOHCH_3$.

The reaction of the three butylenes with sulphuric acid to yield alkylsulphuric esters, and then, by hydrolysis, the corresponding alcohols, is now well known. Much less concentrated acid may be used to effect the reaction than with ethylene and propylene. The use of too concentrated acid results in the formation of undesirable by-products. This reaction will be discussed in detail in Chapter 16, which describes the production of the higher aliphatic alcohols.

The reaction between hydrogen chloride and the three butylenes has been investigated by Coffin, Sutherland and Maass.[52] The rates of reaction with anhydrous liquid hydrogen chloride were shown to differ so greatly that it is possible to utilize this reaction as a means of separating the isomers. Thus, isobutylene is completely converted into tertiary butyl chloride by hydrogen chloride gas at —78° C., while the other two butylenes are scarcely affected. Of the chlorides produced, only the secondary is formed from 1- and 2-butene, while isobutylene yields only the tertiary chloride. In the reaction between 1-butene and 2-butene and hydrogen chloride, a secondary product was also formed which was shown to be an octyl chloride, readily decomposable into octylene and hydrogen chloride. The remarkable activity of isobutylene in combining with halogen acids has been known for many years. Zalessky[53] found that on heating the hydrocarbon with concentrated hydrochloric acid to 100° C. it was converted into tertiary butyl chloride and Favorsky[54] noted that the reaction between hydrogen chloride and isobutylene occurred at 100° C. in the presence of asbestos. The observation of Scheschukoff[55] that isobutylene reacts with aqueous hydriodic acid at 0° C. to yield tertiary butyl iodide was later somewhat elaborated by Michael and Brunel,[56] who found that mixtures of tertiary iodide and tertiary alcohol were simultaneously produced, the composition of the mixture being dependent upon the concentration of the hydriodic acid used. When 60 per cent hydriodic acid was used the product was the iodide almost exclusively but with acids of lower concentration increasing proportions of free tertiary alcohol were found to be present. Various proposals for the direct addition of hydrogen chloride to butylenes have been made, such as those of the T. Goldschmidt A.-G[57] and Blanchet.[58].

The direct combination of butylene with acetic acid was described by the Bataafsche Petroleum Maatschappij.[59] Their method consists in heating a mixture of the olefin, glacial acetic and sulphuric acids, and ferro- or ferri-cyanides (as catalysts) in an autoclave. A 70 per cent yield of butyl acetate and also a small quantity of butyl alcohol is said to result. Frolich and Young[60] suggested passing olefins, particularly butylene, countercurrent to a stream of glacial acetic acid, containing some sulphuric acid, at temperatures of 50° C. or higher. Pressures of 100 to 180 pounds per square inch may be employed. The esters are extracted from the acid with a low-boiling solvent, e.g., pentane or hexane, and the solvent and esters separated by distillation.

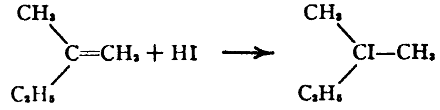
HIGHER OLEFINS

The ease of addition of sulphuric acid to some of the higher olefins is remarkable and the products are the alkylsulphuric esters corresponding to the secondary and tertiary alcohols. These are discussed later in connection with the synthesis of higher alcohols from olefins (Chapter 16).

Much of the earlier work on the direct combination of halogen acids with the higher olefins is of questionable value since the materials treated probably were mixtures of isomeric olefins. Nevertheless, sufficient information was collected to show that the pentenes and hexenes can combine with halogen acids with great ease to yield the corresponding alkyl halides. Wagner and Saytzeff[61] found that 2-pentene reacts readily with aqueous hydriodic acid to yield 3-iodopentane, a similar product being also obtained from 1-pentene. Isopropylethylene combines with hydriodic acid at room temperature to yield the corresponding secondary iodide,

$$(CH_3)_2CHCH{=}CH_2 + HI \longrightarrow (CH_3)_2CHCHICH_3$$

but this reaction does not take place at —20° C. at which temperature methylethylethylene readily combines with hydriodic acid to yield tertiary amyl iodide,



$$\begin{matrix} CH_3 \\ \quad\diagdown \\ \quad\; C{=}CH_2 \\ \quad\diagup \\ C_2H_5 \end{matrix} + HI \longrightarrow \begin{matrix} CH_3 \\ \quad\diagdown \\ \quad\; CI{-}CH_3 \\ \quad\diagup \\ C_2H_5 \end{matrix}$$

Isopropylethylene or methylethylethylene does not react with hydrogen chloride at —80° C. in the absence of a catalyst.[62] However, when aluminum chloride is present, isopropylethylene reacts to yield mostly 2-methyl-3-chloro-butane. The main product from methylethylethylene is 2-chloro-2-methylbutane.

A critical study of the addition of hydrogen bromide to 2-pentene was made by Lucas and Moyse.[63] The pure pentene was distilled between 35° and 37° C.

result being considered in agreement with the prediction made on the basis of the theory of electron displacement). An extended study of orientation in the addition of halogens and hydrogen halides to simple ethylene derivatives has also been made by Ingold and his collaborators.[63a]

Some interesting results have been reported by Piotrowski and Winkler[64] on the addition of hydrogen chloride to unsaturated hydrocarbons. The hydrocarbon mixture used in their experiments was a fraction of cracked gasoline (boiling range of 20° to 40° C.) and contained about 31 per cent by weight of amylenes. The hydrocarbon vapors together with a slight excess of hydrogen chloride were passed over heated catalysts supported on activated charcoal and held in two tubes. When the temperature of the first tube was maintained at 75° C. and that of the second tube at 150° C. the products of the reaction were predominantly secondary chlorides. If the sequence of these temperatures was reversed, then a mixture of all possible chlorides was obtained. The presence of moisture interfered with the formation of the secondary chlorides, while its absence caused no detrimental effects. The catalysts were poisoned by sulphur compounds, and the latter should therefore be removed.

The catalysts employed were the chlorides of bivalent, tervalent, and quadrivalent metals, and could be divided into three groups: (1) ferric and chromic chlorides which were inactive; (2) the chlorides of mercury, copper, cadmium, manganese, bismuth, aluminum and antimony which were only slightly active; and (3) zinc and stannic chlorides which were active, the latter[65] giving a practically quantitative yield of the monochlorides of amylene.

It is said that amylene and acetic acid react at ordinary temperatures in the presence of zinc chloride.[66] The yield of acetates is low, however, because of the formation of polymers. Nernst and Hohmann[67] have shown that, when heated in sealed tubes at 100° C., amylene will combine with di- and tri-chloracetic, tri-chlorolactic, salicylic and benzoic acids. With trichloracetic acid a maximum yield of 88 per cent of the trichloracetic amyl ester was obtained.

The preparation of amyl acetate by the direct esterification of amylene is described by Brooks.[68] Sucharda and Mazonski[69] state that amylene and hexene, occurring in low-boiling cracked petroleum distillates, can be converted almost quantitatively into the corresponding secondary and tertiary formates by formic acid in the presence of sulphuric acid.

The combination of the higher open-chain olefins with organic acid takes place much more readily than with the lower homologues. Béhal and Desgrez[70] brought about this direct combination by heating the reactants together in sealed tubes. Thus, on heating caprylene with three volumes of glacial acetic acid for 24 hours at 300° C. a good yield of octyl acetate was obtained. Under similar conditions heptylene yielded a secondary heptyl acetate, while on heating allyl acetate with glacial acetic acid, at 275° to 285° C., there was produced the diacetate of propylene glycol,

$$CH_3CH(OOCCH_3)CH_2(OOCCH_3).$$

In the direct hydration of various olefins under the influence of aqueous oxalic acid solutions as observed by Miklaschewsky,[71] the oxalic acid ester is probably an intermediate product. The direct combination of olefins with organic acids is facilitated by the addition of dehydrating agents such as zinc chloride or sulphuric acid to the mixture. Thus, on allowing equimolecular quantities of hydrocarbon and organic acid to stand at 20° C. for 24 hours in the presence of anhydrous zinc chloride (12 to 20 grams of zinc chloride per 100 grams of hydrocarbon), Kondakow[72] found that considerable combination took place, the yield of ester being 20 per cent or more. In this way trimethylethylene yields the acetate of dimethylethylcarbinol. Bertram and Walbaum[73] used a mixture of glacial acetic acid and 50 per cent sulphuric acid. This method is especially applicable to the terpene series, e.g., the conversion of camphene into isobornyl acetate and of pinene into bornyl esters.

Many cyclic olefins of the terpene class are known to react very readily in glacial acetic acid or ether solution. Thus, for example, sylvestrene[74] with two double bonds in its molecule combines with hydrogen chloride to yield a crystalline dihydrochloride, and carvestrene[75] similarly combines with two molecules of hydrogen bromide in glacial acetic acid solution to yield a dihydrobromide thus: $C_{10}H_{16} + 2HBr \rightarrow C_{10}H_{18}Br_2$, two double bonds being saturated in the process. The addition of halogen acids to pinene and other terpene hydrocarbons is well known.

The fact that the unsaturated cyclic hydrocarbon pinene (present in turpentine) can combine directly with acids[76] to yield bornyl esters has provided a commercial method for the synthesis of camphor. The esterification of pinene can also be effected by organic acids. Thus, bornyl trichloroacetate is readily prepared by heating pinene with trichloroacetic acid,[77] and bornyl oxalate by heating pinene with anhydrous oxalic acid at 100° C. The bornyl acetate can be hydrolyzed by lime and the borneol obtained can then be oxidized to yield camphor.[78] Esters of borneol and isoborneol are made by the reaction of formic or acetic acid with camphene in the presence of boron fluoride.[79] According to Schwyzer[80] the technical esterification of pinene is now carried out by means of oxalic acid or, better, by salicylic acid, the use of the latter resulting in the production of less by-products. The bornyl esters are then hydrolyzed to borneol which is oxidized to camphor.

Chapter 13

Production of Ethyl Alcohol from Ethylene

The production of most of the primary alcohols is carried out by fermentation processes, by destructive distillation of carbonaceous material, or by the saponification of certain natural esters. From petroleum hydrocarbons as raw materials only the first two primary alcohols are produced on a large scale, namely methyl alcohol or methanol and ethyl alcohol or ethanol.

As shown in the preceding chapters the addition of the elements of water to olefins, either by direct hydration or indirectly by means of acids, results in the formation of alcohols. Ethylene is the sole olefin which under these conditions yields only a primary alcohol, ethyl alcohol; all the other olefins yield mixtures of primary and secondary, or secondary and tertiary alcohols.

Ethyl alcohol is a substance of immense industrial value as a solvent, as a chemical intermediate, and as a fuel for internal combustion engines. It still is very largely manufactured at the present time by the fermentation of various types of carbohydrate materials. It has long been known that ethyl alcohol could be prepared from ethylene in a number of ways but the industrial application of these reactions has until recently been prevented by economic considerations. The ethylene of coke-oven gas, amounting to only 3 per cent by volume of that gas, was the main source of that material until a decade ago. During the past few years large quantities of ethylene and other olefins have been produced in commercial cracking operations, a factor which has greatly stimulated interest in the various processes for the manufacture of alcohols from the lower olefins.

Two procedures are available for the conversion of ethylene into ethyl alcohol, namely:

(1) Direct hydration according to the reaction:

$$CH_2{=}CH_2 + H_2O \longrightarrow C_2H_5OH$$

This has been discussed in some detail (Chapter 11) and does not appear to be very promising, although continuing to be a subject of active investigation.

(2) Combination of ethylene with various acids, followed by hydrolysis of the resulting ethyl ester.

In this chapter the well-known sulphuric acid process will be discussed since this alone seems to have attained a measure of success. The reactions involved in the production of ethylsulphuric acid followed by hydrolysis of this substance may be represented by:

$$C_2H_4 + H_2SO_4 \longrightarrow C_2H_5HSO_4$$
$$C_2H_5HSO_4 + H_2O \longrightarrow C_2H_5OH + H_2SO_4$$

The reaction between ethylene and sulphuric acid to yield ethylsulphuric acid was studied in Faraday's laboratory as early as 1827 by Hennell, who used gas containing olefins and suggested the production "of either ether or alcohol according to circumstances which are under perfect control".[1]

---

[1] *Proc. Roy. Soc. (London)*, 1828, 118, 365.

Berthelot,[2] however, was the first to investigate the reaction from the point of view of the synthesis of alcohol from gases containing ethylene. He found that the absorption of ethylene by concentrated sulphuric acid was very slow at ordinary temperatures even with good agitation. More rapid absorption occurred at high temperatures though some loss of acid from oxidation and charring of the olefin also took place. In another publication Berthelot[3] described his experiments on the velocity of absorption of ethylene in sulphuric acid as well as the separation of olefins from illuminating gas by means of iodine. He was able to show that alcohol could be made by processes other than fermentation. The absorption of olefins by sulphuric acid and their subsequent conversion into ether was also discussed.[4]

Some interesting views were expressed by Payen,[5] who criticized the attempts being made at that time to produce alcohol from the olefins in illuminating gas.

> "A new process for the production of alcohol from illuminating gas is said to have been recently discovered whereby one hectoliter of alcohol can be made for 25 francs. As a matter of fact one liter of alcohol produced from oil-forming gas was shown at the London Industrial Exhibition; this oil-forming gas, however, was the result of decomposing alcohol according to usual laboratory methods, and as is well known the content of this same gas in illuminating gas does not exceed 10 per cent. The costs of making this liter of alcohol, which was exhibited in London, are said to have amounted to not less than 100 francs. . . . There is also a rumor that alcohol production is being carried out on a large scale at Saint Quentin, and that coal is fed into one side of the apparatus while alcohol is discharged on the other side. According to reliable information which I have received, only one or two liters of alcohol have been taxed up to the present and furthermore it has not yet been definitely proved that this alcohol was produced by the application of the new method.
>
> "Benjamin Corenwinder has shown in a letter to Pasteur that *a priori* this method of production would be very difficult and expensive, because one part of alcohol requires ten parts of sulphuric acid, and furthermore the purification of the alcohol is not an easy task. This purification, however, can be accomplished by means of olive oil, which after continued use imparts a very rancid odor to the alcohol.
>
> "I therefore do not believe the rumor mentioned above has any serious basis, and that alcohol production from oil-forming gas, while scientifically possible, has not yet been developed into a practical and economical process."

According to Goriainow and Butlerow,[6] ethylene is not dissolved by sulphuric acid at ordinary temperatures but at 100° C. (and still better between 160° and 175° C.) the gas is very rapidly absorbed. By subsequently diluting and distilling the acid liquor they obtained a considerable quantity of alcohol. Later work appears to indicate, however, that at the higher temperatures mentioned considerable charring and oxidation occur.

Fritzsche[7] was the first to attempt the large-scale manufacture of ethyl alcohol and diethyl ether from ethylene by the sulphuric acid process. The source of ethylene was initially coal gas stripped of its higher unsaturated hydrocarbon content by washing with 62° to 64° Bé sulphuric acid at ordinary temperature. Ethylene was absorbed from this purified gas in hot concentrated sulphuric acid at temperatures of 110° to 120° C., at which temperature the absorption is rapid and the decomposition of the resulting ethylsulphuric acid slight. According to Fritzsche, the resulting ethylsulphuric acid may be worked up at will into alcohol, ether or esters of organic acids. Alcohol or ether may be obtained by heating with water and esters by the addition of the salts of organic acids. The cost of reconcentrating the dilute acid was considered to be so great as to make it doubtful if alcohol could be produced commercially in this way.

The absorption of ethylene in sulphuric acid, followed by the addition of water, distilling the mixture, and determining the quantity of alcohol in the distillate is the basis of a method for the quantitative estimation of ethylene in gas mixtures.[8]

The production of diethyl ether from the mixture of sulphuric and ethylsulphuric acids obtained by absorbing ethylene in concentrated sulphuric acid was discussed by Fritzsche.[9] The method involves the use of four distilling vessels *A, B, C,* and *D,* connected in such a way that the vapors evolved from *A* pass through the liquids contained in *B, C,* and *D,* and are condensed beyond *D.* Each vessel is charged with the same volume of ethylsulphuric acid mixture, the liquid in *A* being diluted with 35 per cent of water, that in *B,* with 22 per cent, that in *C,* with 10 per cent, and that in *D* being undiluted. The contents of *A* are strongly heated and the liquid in *B* is only slightly warmed with the result that pure ether passes beyond *D* and is condensed. When the liquid in *A* is sufficiently concentrated it is run out, the liquid in *B* transferred to *A,* that in *C* to *B,* and that in *D* to *C;* after which *D* is charged with a further quantity of undiluted acid. The dilutions in the first three containers are adjusted as before and the distillation continued until *A* is again concentrated. Instead of removing the charge in *A* after each operation, the process can be made to work continuously by using an apparatus in which the concentrated acid passes in a constant stream into the vessel, water being introduced continuously into the apparatus to maintain the correct dilution.

Later Fritzsche[10] recorded some results obtained with his process in the United States where large quantities of oil gas, containing 22 per cent or more of ethylene, were available. The most important consideration was the removal of higher olefins and diolefins by a preliminary wash with 66° Bé sulphuric acid at temperatures below 40° C. Brooks[11] removed higher monolefins and diolefins from cracked oil gas by subjecting the mixture to pressures of 300 to 550 pounds per square inch. At these pressures a large amount of undesirable compounds condense out leaving a gas containing a substantially high ethylene fraction.

In the course of an investigation of the methods of analysis of gaseous unsaturated hydrocarbons, Lebeau and Damiens[12] observed that certain substances dissolved or suspended in concentrated sulphuric acid were capable of accelerating the absorption of ethylene to a marked degree. It was found, for example, that solutions of vanadic and uranic acids, as well as uranyl sulphate, in sulphuric acid were excellent catalysts, and that tungstic and molybdic acids possessed somewhat less catalytic power. These catalysts were only active after being reduced by mercury or some other metal in sulphuric acid solution, the reduction being frequently accompanied by marked color changes.

An attempt to manufacture alcohol by the sulphuric acid reaction was made by Bury and Ollander[13] and Tidman[14] at Skinningrove (England) about 1919 to 1921, using coke-oven gas containing about 2 per cent of ethylene as the raw material. The best strength of acid was found to be between 95 and 95.8 per cent and the optimum temperature range 60° to 80° C. The absorption was carried out in towers packed with fused silica but mechanical agitators were considered more suitable. The interesting observation was made that the addition of silica to the sulphuric acid increased the speed of absorption by 5 per cent. This was considered to be a catalytic reaction since, in a repetition of the experiment under similar conditions except that the silica was coated with a slime of lead sulphate, the absorption was not so rapid. The efficiency of absorption was about 70 per cent, and after saturation the acid was diluted to 64 per cent with water and distilled under a vacuum of 26.5 inches, the temperature rising from 94° to 146° C. during the distillation. This operation could be performed satisfactorily without frothing. The acid residue showed 80 per cent sulphuric acid and the distillate contained 15 per cent alcohol. Attempts to recover the alcohol from the absorption product by means of a countercurrent flow of acid and superheated steam failed because of the large amounts of froth produced. Concentrated alcohol produced in this way possessed an objectionable odor which was traced to the presence of certain impurities, notably diethylene disulphide, resulting from the action of ethylene on the hydrogen sulphide present in the gas. Commercial development was handicapped by the large amount of acid required, namely 6 to 7 pounds of acid per pound of ethylene, and the expensive reconcentration necessary.

Our knowledge of the reaction between ethylene and sulphuric acid has been extended by the work of Plant and Sidgwick,[15] who studied the influence of various factors on the absorption of ethylene by acids of various concentrations without catalysts. Both the acid concentration and the temperature are important. Apart from decomposition, three successive stages were observed in the absorption process corresponding to (1) solution of ethylene in the liquid, (2) its reaction with sulphuric acid to yield ethylsulphuric acid, and (3) further interaction between ethylene and ethylsulphuric acid to yield diethyl sulphate. It was found that some diethyl sulphate was formed before all the sulphuric acid had been converted into ethylsulphuric acid, diethyl sulphate appearing after about 20 per cent of ethylene was absorbed. Considerable blackening occurred at 100° to 126° C. with 99 per cent acid, and absorption in oleum (containing 14 per cent sulphur trioxide) at these temperatures yielded large amounts of carbyl sulphate,  $\begin{matrix} CH_2OSO_2\diagdown \\ | \qquad\quad O \\ CH_2SO_2\ \diagup \end{matrix}$, a substance not hydrolyzable to alcohol.

A study of the reactions involved was made by Damiens,[16] who, with de Loisy, is responsible for the application of certain catalysts to the absorption process.[17] Damiens investigated the effects of various factors, namely, concentration of acid, efficient contact of gas with acid, partial pressure of the ethylene, temperature of absorption and the influence of catalysts. He found that, other factors being the same, the velocity of absorption in 99.5 per cent acid is 3 to 5 times greater than that in 95.5 per cent acid. Intensive agitation and good contact of gas with acids for a sufficient period of time favor rapid absorption. The velocity of absorption is diminished in roughly the same proportion as the partial pressure of ethylene. Raising the temperature from 25° to 60° C. increased the rate of absorption threefold. New and efficient catalysts for the reaction were found in cuprous salts, such as cuprous oxide, sulphate and chloride, all of which accelerate absorption. The addition of 5 per cent of cuprous oxide to 95 per

[15] *J.S.C.I.*, 1921, 40, 14T.

[16] *Compt. rend.*, 1922, 175, 585; *Bull. soc. chim.*, 1923, 33 (4), 71; *Chem. Abs.*, 1923, 17, 259.

[17] *Chim. Ind.*, 1923, 664, (Special Number, May 1923); *Chem. Abs.*, 1923, 17, 3318.

cent acid causes a rapid absorption of ethylene at 40° C. giving a 94 per cent yield of ethylsulphuric acid. Cuprous oxide dissolved in 98 per cent acid produces an identical reaction but continued introduction of ethylene yields diethyl sulphate. The proportion of diethyl sulphate is higher at lower temperatures, and Damiens considered that the following equilibrium was set up:

$$H_2SO_4 + (C_2H_5)_2SO_4 \rightleftharpoons 2C_2H_5HSO_4$$

Damiens observed the remarkable fact that sulphuric acid heated for a short time with cuprous oxide (until white fumes are evolved) and then cooled absorbed ethylene rapidly at 15° to 20° C. in the presence of mercury. The products consisted mainly of hydrocarbons from the polymerization of ethylene. To explain the catalytic activity of cuprous salts Damiens assumed the formation of complexes of the type $Cu_2SO_4 \cdot n(C_2H_4)$, which could either combine with the sulphuric acid to yield ethylsulphuric acid or with themselves to form higher hydrocarbons.

It is interesting to note that Böeseken and Max[18] separated a mixture of saturated and unsaturated hydrocarbons from the products of the absorption of ethylene in 93 to 95 per cent sulphuric acid containing 5 per cent of cuprous sulphate and 2 per cent of mercurous sulphate. The saturated hydrocarbons of low boiling point were probably paraffins.

Neumann[19] also recorded some experiments on the absorption of ethylene by sulphuric acid. The formation of ethylsulphuric acid increased with the concentration of the acid employed until 99 per cent was reached. Above that point the yield fell off sharply and carbyl sulphate made its appearance. Addition of catalysts increased the speed of absorption but at the same time produced undesirable by-products.

The search for other catalysts of the reaction between ethylene and sulphuric acid led to the conclusion by Gluud and Schneider[19a] that silver sulphate is an excellent material for this purpose. The addition of this compound (the most favorable concentrations being ½ to 1 per cent by weight) to sulphuric acid makes it possible to attain a much greater absorption at 40° C. than in ordinary acid at 80° C. The catalytic activity of silver sulphate as observed by Gluud and Schneider was also independently noticed by Lommell and Engelhardt,[20] who expressed the opinion that the reaction proceeds in two distinct stages, namely (1) the addition of ethylene to the silver salt which occurs rapidly even at room temperatures, and (2) the formation of ethylsulphuric acid which is slower but attains a satisfactory velocity at 40° C. Ethylene can be recovered unchanged from the initial addition compound by evaporation. Such addition compounds are also formed in aqueous solutions in the absence of sulphuric acid.

The description of an interesting process for the production of ethyl alcohol from ethylene in refinery gases has been given by Gerr, Pipik and Mezhebovskaya.[21]

> The gases used contained about 30 per cent unsaturates, and the underlying principle was the separation of ethylene by activated charcoal.[22] When the gases are passed through a large excess of charcoal the entire mixture is first absorbed, and then with

Khoz.*, 1932, No. 7, 82; *Chem. Abs.*, 1932, **26**, 5745) regenerated the activated charcoal by treatment with steam at 200° to 360° C.

[22] For the theoretical basis of this use of activated charcoal, see Hill, *Petroleum World* (*Los Angeles*), 1929, **14**, No. 1, 101, 110; *Chem. Abs.*, 1929, **23**, 2285.

continued passage of the gas those hydrocarbons with the lower vapor pressures displace those with the higher vapor pressures. Saturated hydrocarbons are the least firmly held by the charcoal, and unsaturated hydrocarbons, containing double or triple bonds, are the most firmly held. Ethylene, the olefin of lowest molecular weight, is more easily displaced than any of its homologues.

An almost quantitative separation of ethylene from other unsaturated hydrocarbons could be obtained when a ratio of one liter of gas to 4 grams of charcoal was used. Absorption of the exit gas from the charcoal in sulphuric acid (d. 1.84) followed by hydrolysis and distillation yielded practically pure ethyl alcohol. For less pure or technical alcohol, the ratio could be decreased to 4 liters of gas to 5 grams of charcoal. The technical alcohol, however, always possessed a yellowish color and a slightly unpleasant odor [23] together with a slightly higher boiling point (78.6° C. at 760 mm.).

The gases were absorbed in concentrated sulphuric acid (d. 1.84) containing 1 per cent of silver, and the yield of alcohol (based on the raw gas) was about 13 to 15 per cent. Decreasing the quantity of silver catalyst materially decreased the yield of alcohol. The temperature of the acid during absorption was maintained at about 40° C. In the preparation of pure alcohol, the acid remaining after hydrolysis and distillation was transparent and clear, and the silver could be recovered either by electrolysis or by precipitation with hydrochloric acid. The recovery of the silver from the preparation of technical alcohol was complicated by the fact that the sludge of polymerization products formed during the reaction contained a large portion of the silver, and that some of the silver separated on the walls of the scrubber, leaving only a very small proportion dissolved in the acid layer. The sludge could be dissolved in nitric acid, from which the silver was recovered by precipitation.

Attempts were made to substitute an iron catalyst (the walls of the acid-scrubbing unit) for silver at a temperature of 80° to 95° C. The yield of alcohol was much lower, being about 8 per cent (based on the raw gas). On the basis of the ethylene content about 60 per cent utilization was obtained with the silver catalyst, and only 40 per cent with the iron catalyst.

The charcoal could be regenerated by treatment with superheated steam at 250° to 300° C. for several hours.

Dalin and Gutuirya [24] used the method of Gerr, Pipik and Mezhebovskaya in an investigation of alcohol manufacture from cracked gas. The product consisted of 90 per cent ethyl alcohol. However, only 5.5 to 6.2 per cent of the theoretical yield was obtained due to the faulty equipment and unsatisfactory regeneration of the charcoal.

The absorption of ethylene by ortho-, pyro-, and metaphosphoric acids was accelerated by the addition of cuprous oxide or silver sulphate.[25] Ethyl dihydrogen orthophosphate was formed with orthophosphoric acid and possibly also from pyrophosphoric acid.

The possibility of employing equal weights of chlorosulphonic acid and 100 per cent sulphuric acid for absorbing ethylene from coke-oven gas was examined by Traube and Justh.[26] The chlorosulphonic acid absorbs about 82 per cent of the theoretical quantity of ethylene yielding ethyl chlorosulphonate, which on hydrolysis is converted partly to alcohol and sulphuric and hydrochloric acids, and partly to ethyl chloride and sulphuric acid.

The effect of increasing the pressure of ethylene above atmospheric in the reaction with sulphuric acid was first investigated by Maimeri.[27] Experiments with 100 per cent sulphuric acid and 98 per cent ethylene at ordinary temperature showed that the amount of diethyl sulphate formed increased with increases in pressure, the absorption becoming ultimately so rapid that it was necessary to cool the reaction vessel. On dilution of the reaction product with iced water diethyl sulphate separated and was distilled under reduced pressure. The aqueous

[23] Bataafsche Petroleum Maatschappij (French Patent 744,119, 1933; *Chem. Abs.*, 1933, **27**, 3943; British Patent 393,152, 1932; *Brit. Chem. layer was neutralized with sodium hydroxide, evaporated to dryness, and the sodium ethyl sulphate extracted with alcohol. At 3.5 atmospheres pressure of ethylene the yields of diethyl sulphate and ethylsulphuric acid were 35 per cent and 51 per cent respectively (based on the sulphuric acid used), while at 10 atmospheres pressure the figures were 62 per cent and 30 per cent. The total yield of alcohol (based on sulphuric acid) was 57.5 per cent at 3.5 atmospheres and 76.7 per cent at 10 atmospheres, the latter being three times the best obtained by previous workers. Maimeri considered this method to be the most economical for the production of diethyl sulphate.

Thau and Bertelsmann [28] experimented with a coke-oven gas which had been washed with oil to remove benzol and freed of hydrogen sulphide. It was dried with sulphuric acid of 60° Bé and scrubbed with acid of the same strength, at temperatures varying from 60° to 135° C., in lead-lined iron containers filled with quartz lumps. The yield of alcohol diminished from 20.67 grams per cubic meter at 70° C. to 9.16 grams per cubic meter at 135° C. At 60° C. it was 19.32 grams per cubic meter. The ethylene content of the exit gas diminished from 0.85 per cent at 60° C. to 0.47 per cent at 135° C. As the temperature was increased considerable decomposition of the ethylsulphuric acid began to take place, sulphur dioxide being formed at 90° C. and some ether at 110° C.

The recovery of alcohol from the ethylene of coke-oven gas was discussed by Gluud, Schneider, and Keller,[29] who stated that the use of silver sulphate as a catalyst materially increases the probability of obtaining alcohol commercially from this source. It is essential however to eliminate the gaseous heavy hydrocarbons present in the raw gas and to reduce the quantity of water necessary for hydrolyzing the ethylsulphuric acid. Later Gerr and Popov [30] used the catalytic activity of silver sulphate for the production of alcohol from the ethylene present in cracking gas. A gas containing 54 per cent of paraffin hydrocarbons, 12.2 per cent of hydrogen, and 33.8 per cent of unsaturated hydrocarbons was passed over calcium chloride, then over wood charcoal (to remove the higher homologues of ethylene), and finally through an absorption tube, kept at 40° C. and containing glass beads or glass wool, in which a stream of a 1 per cent solution of silver sulphate in 94 per cent sulphuric acid absorbed the ethylene. In this manner 33.8 grams of alcohol were obtained from 300 liters of gas.

Behrens [31] described the preparation of ethyl alcohol, as well as acetaldehyde, from ethylene in the gases obtained by the destructive distillation of coal, lignite, peat, wood and similar materials. The gases are scrubbed with sulphuric acid, and the ethylsulphuric acid is either (1) hydrolyzed to yield alcohol, or (2) heated to give purified ethylene which can be oxidized catalytically to acetaldehyde.

DeLattre [32] proposed a method of treating coal-distillation gases by which they are passed, freed of the usual impurities, through concentrated sulphuric acid in the presence of vanadium or uranium oxides. The ethylsulphuric acid formed is converted into alcohol by hydrolysis. The residual gas containing methane and its homologues can be chlorinated photochemically and the chlorohydrocarbons then transformed into the corresponding alcohols by reaction with alkalies.

In 1919, Damiens, deLoisy and Piette [33] described a process for the manufacture of alcohol and ether from ethylene. The ethylene remaining in coal or coke-oven gas, after removal of ammonia, benzene and ethylene homologues, was absorbed in 66° Bé sulphuric acid (best at 100° to 120° C.) which contained one or more catalysts. Good results were obtained with acid containing 1 to 2 per cent of phosphoric acid anhydride, or 1 to 5 per cent of ferrous or cuprous sulphate. Before absorption of ethylene, the gas is dehydrated and freed from traces of higher reactive hydrocarbons. The acid, after absorption, is diluted and distilled to give either alcohol or ether or both. For example, when the absorbing acid was diluted with 60 per cent of its weight of water, distillation yielded a mixture of 22 per cent ether and 78 per cent alcohol. By diluting with 14 per cent of water and distilling, a mixture of 4 per cent ether and 96 per cent alcohol was obtained.

In a description of the Skinningrove Iron Co.'s process, developed by Bury,[34] a number of details were presented. Cooled coke-oven gas is freed of hydrogen sulphide, and then of water by passing it through sulphuric acid. It is reheated in a heat exchanger and the ethylene absorbed in concentrated sulphuric acid at 60° to 80° C. in a series of scrubbers. The ethylsulphuric acid flows to a heat exchanger and thence to an alcohol still to which superheated steam is supplied. Ether may be recovered instead of alcohol or the solution oxidized electrolytically to yield acetic acid. Plant tests were said to have proved a recovery of 90 per cent of the ethylene (from gas containing 2 to 3.5 per cent), with 70 per cent as a safe working basis. Of the ethylene absorbed at least 70 per cent can be converted into absolute alcohol, an overall recovery of 50 per cent.

In making diethyl sulphate from ethylene and sulphuric acid, Curme[35] took advantage of the greater volatility of this compound. A rapid stream of ethylene is passed through sulphuric acid (93 per cent) at about 100° C. Ethylsulphuric acid is the initial product, but continued passage of the gas yields diethyl sulphate which is carried over with the stream of ethylene and condensed. After separation from some water (also carried over by the ethylene), diethyl sulphate is recovered in a substantially pure condition. Prolonged passage of the ethylene results in practically all of the sulphuric acid being converted into diethyl sulphate.

In the preparation of this same compound from ethylene and sulphuric acid, Maimeri[36] made use of pressures greater than atmospheric. Ethylene, free as far as possible from diluting gases, is treated under 15 atmospheres pressure at 55° to 65° C. (in the absence of catalysts) with 85 per cent sulphuric acid. Good stirring is necessary and the temperature must be maintained below 75° C. The reaction product is poured onto ice and separates into two layers, the lower of which consists of almost pure diethyl sulphate in a yield of 80 per cent of the theoretical.

The absorption of ethylene in dilute sulphuric acid (less than 80 per cent strength) at increased temperatures and pressures has been proposed by Joshua, Stanley and Dymock.[37] The reaction is carried out in the presence of materials (e.g., pumice, porcelain, or silica gel, or a compound of phosphoric acid and boric anhydride) which increase the surface contact of the reacting substances. A liquid surface extender, such as a refined mineral oil, or a combination of solid and liquid contact agents, may be employed simultaneously. The temperature at which absorption takes place determines the product of the reaction. For ex-

ample, when ethylene is absorbed in dilute sulphuric acid at 90° C. and 50 to 100 atmospheres the main product is ethyl alcohol, while at temperatures above 100° C., at 50 atmospheres pressure, a mixture of ethyl ether and ethyl alcohol is obtained.[38] Brooks[39] sulphates ethylene or propylene by treating the gaseous olefin with 80 to 95 per cent sulphuric acid, under a pressure greater than 250 pounds per square inch, and at temperatures of 30° to 125° C.

A continuous method for the production of ether free from alcohol was described by Fritzsche.[40] In heating ethylsulphuric with water, ether vapors are produced along with the alcohol vapors. This mixture of ether and alcohol vapors is introduced into vessels containing ethylsulphuric, sulphuric acid or both. The alcohol vapors coming into contact with the ethylsulphuric acid are converted into ether. Bradley[41] recommended absorbing ethylene in concentrated sulphuric acid at about 140° C. Superheated steam, at a temperature higher than the boiling point of the acid, was then introduced into the mixture. This latter step keeps the acid strength constant during the distillation of the ether vapors, and permits re-circulation of the acid without further concentration.

Hydrolysis and distillation of ethylsulphuric acid may be accomplished by passing sulphuric acid containing ethylsulphuric acid and a stream of ammonia gas into a saturator in which dilute sulphuric acid is present. The dilute acid hydrolyzes the ethylsulphuric acid, and the heat of the reaction between ammonia and sulphuric acid is sufficient to effect distillation of the alcohol.[42]

Basore[43] developed a process having several features worthy of comment. The hydrolysis of ethylsulphuric acid by water to yield alcohol is relatively slow and requires a longer time than had hitherto been employed, and when the concentration of ethylsulphuric acid in the scrubbers is permitted to exceed 30 per cent (by weight) of the sulphuric acid, the subsequent dilution and treatment of the acid liquor yields considerable quantities of ether. Recognizing these facts, Basore preferred to discontinue the ethylene absorption when the ethylsulphuric acid content had risen to 10 to 20 per cent of the sulphuric acid and conducted the process as follows: The purified gas containing ethylene (e.g., coke-oven gas) is washed with sulphuric acid of 66° Bé, at a temperature of 70° to 80° C. When the ethylsulphuric acid content has risen to 10 to 20 per cent (by weight of the sulphuric acid), the acid is run into another vessel where a volume of water is added approximately 60 per cent of that of the sulphuric acid-ethylsulphuric acid mixture. This is heated for 60 minutes at a temperature of 100° to 120° C. to effect the complete hydrolysis of the ethylsulphuric acid, and is then distilled to yield alcohol.

A number of substances which catalyze the absorption of ethylene in sulphuric acid are mentioned by Damiens, de Loisy and Piette.[44] These consist of the lower oxides or salts of metals exhibiting more than one valence state, as for example iron, nickel, cobalt, cerium, manganese, chromium, copper, lead,

mercury, titanium or tin. Ferrous sulphate, cuprous chloride, cuprous oxide, and cuprous sulphate offer the advantage that they are insoluble and may be easily removed from the acid by filtration and used again. In the process alcohol is made from the ethylene of illuminating gas by passing the purified gas through a column (filled with pumice) in which it is washed by a stream of 66° Bé sulphuric acid, containing 5 per cent of cuprous oxide as catalyst, and maintained at a temperature of 35° to 40° C. In the presence of the cuprous salts diethyl sulphate begins to form at low temperatures (0° to 15° C.) when the concentration of ethylsulphuric acid is only 25.6 per cent instead of 75 per cent as normally.

The use of silver or silver salts as catalysts for the absorption of ethylene in 96 per cent sulphuric acid is suggested by Engelhardt, Lommel and Ossenbeck.[45] The silver may be employed in a colloidal state or as a salt or complex compound. The addition of 0.1 to 0:2 per cent of silver sulphate to 96 per cent acid is said to increase the volume of ethylene absorbed 13 times. Furthermore the rapidity of absorption is increased still more by raising the temperature or by the addition of small quantities of foam-producing or emulsifying materials (olive oil, castor oil, Turkey-red oil, chloroform, carbon tetrachloride or stearic acid). The use of foam-producing substances has also been suggested by the I. G. Farbenindustrie A.-G.[46]

In a process for the hydration of olefins McElroy[47] used sulphuric acid of catalytic strength, i.e., of a concentration sufficient to absorb the olefin and simultaneously give it up in the form of alcohol. He proposed to effect this reaction in a tower where the olefin gases are scrubbed countercurrently with a stream of acid. The concentration of the acid is adjusted so that it is less than catalytic strength at the end where the vapors leave the column and above catalytic strength at the other end where the gas first comes in contact with the acid. The temperature is regulated so that alcohol and water vapors are carried over with the gas stream. To replace water removed in this manner, continuous small additions of water or steam are made to the acid bath.

In a similar manner, Wibaut and Diekmann,[48] using an absorption tower, investigated the behavior of ethylene with acids of varying concentrations. The tower was heated electrolytically, allowing a means of controlling the temperature. Water vapor was added to the ethylene gas in order to keep the acid concentration constant. On the passage of 5 liters of ethylene using 65 per cent sulphuric acid at a temperature of 150° to 160° C., the distillate contained 0.21 gram of alcohol; 0.08 gram more alcohol was obtained on dilution and distillation of the acid. In a second experiment under the same conditions 4 per cent of the ethylene was converted. Using 55 per cent acid, only 0.01 gram of ethyl alcohol was found in the distillate. With acid of 70 per cent strength 0.32 gram of alcohol was present on dilution and distillation of the acid, no alcohol, however, being observed in the distillate. In this latter experiment only 3 liters of ethylene were passed through the reaction chamber.

The Compagnie de Béthune[49] described the production of ethylsulphuric acid by the absorption of ethylene in sulphuric acid of about 94 per cent concentration at 90° to 95° C. The ethylene or gas containing ethylene is circulated continuously through a drying tower and a sulphuric acid column containing Raschig rings or other packing materials and heated externally. A modification[50] consists in using hot concentrated sulphuric acid containing a constant proportion of ethylsulphuric acid (corresponding to an ethylene content of 11 to 18 per cent). It is stated that this mixture absorbs ethylene more rapidly than sulphuric acid alone. A further improvement[51] is realized by passing ethylene through a series of absorption vessels, maintained at successively higher temperatures. Each vessel is supplied independently with fresh sulphuric acid at such a rate as to maintain the concentration of ethylsulphuric acid at its optimum value for absorption purposes.

[49] British Patent 199,007, 1923; *Chem. Abs.*, 1924, **18**, 274.

Taveau[52] suggested conducting a mixture of olefins (such as cracking gas) through a series of absorption vessels containing sulphuric acid in increasing concentrations. The first two vessels are kept at a temperature of 30° C. and in these propylene and butylene are absorbed. In the last vessel ethylene is absorbed in 98 per cent acid at approximately 100° C.

The production of alcohol from the ethylene of coal gas by absorption in chlorosulphonic acid or fluorosulphonic acid has been described by Traube.[53]

The autocatalytic action of ethylsulphuric acid in accelerating the absorption of ethylene in sulphuric acid was utilized by Compton.[54] Ethylene is absorbed in sulphuric acid containing 20 to 90 moles of ethylene per 1000 moles of sulphur trioxide and the composition of the bath is held within the desired limits of concentration by frequent additions of fresh acid.

Bonn[55] liquefied coke-oven gases by cooling in stages and thereby obtained a mixture of liquefied methane and ethylene, which is separated by fractional distillation. The ethylene is purified and further treated by the usual methods for the production of ethyl alcohol or other ethyl derivatives.

While investigating the problem of the utilization of coke-oven gas as a source of ethyl alcohol, the Compagnie de Béthune[56] developed a process for separating a mixture of ethane and ethylene from that gas by liquefaction at —140° to —200° C. The distilled ethylene is absorbed in sulphuric acid and the residual ethane is thermally dehydrogenated at 600° to 800° C. to yield more ethylene. The utilization of the ethane of coke-oven gas is said to increase the yield of alcohol from distillation gases of coal by 30 per cent.

The Bataafsche Petroleum Maatschappij[57] used various catalysts for accelerating the absorption of ethylene in sulphuric acid, and for suppressing undesirable side reactions of the ethylene homologues. In one procedure various cyanogen compounds are suggested for this purpose, among them potassium ferro- and ferricyanides, tetraethyl ferrocyanide, sulphoferricyanic acid, sodium nitroprusside and prussoarsenite, and sodium ferrocarbonylpentacyanide. Other catalysts are compounds of the metals osmium, iridium, platinum, ruthenium, rhodium, palladium, copper, iron, cobalt or nickel.[58] Those metals or compounds which are insoluble in concentrated sulphuric acid may first be brought into a soluble form by converting them, for example, into soluble complex compounds with carbon monoxide or nitric oxide. It is also recommended that emulsifying agents or substances (ethyl alcohol, nitrobenzene, acetic acid or ether) which increase the solubility of ethylene in the acid be added. The metals of the platinum group themselves are active catalysts in a finely divided or colloidal form, as when precipitated on a carrier such as carbon black, silica gel or decolorizing clay.[59] The complete absorption of ethylene can be carried out by passing the gas, at a rate of 3 liters per hour into a solution of, for example, 5 grams of platinum dichlorodiphenylisonitrile in 100 cc. of 96 per cent sulphuric acid at a temperature of 160° C. About 90 per cent ethylene is absorbed when the rate is increased to 5 liters per hour.

The addition of some salts, particularly chlorides, to alcohol often results in the decomposition of both salt and alcohol. For example, aluminum chloride when added to either methyl or ethyl alcohol gives a violent evolution of hydrogen chloride. Ferric chloride does not react as rapidly, though at 50° C. its saturated solution yields chloroform and a dark red iron precipitate. Chloroform is also obtained slowly on boiling a saturated solution of cupric chloride in ethyl alcohol.[59a]

As pointed out, a number of outstanding attempts have been made, particularly by Fritzsche, Bury and Ollander, and Damiens and deLoisy, to apply the sulphuric acid process to large-scale production of ethyl alcohol from ethylene, apparently without much success. Commercial operation is hindered principally by the necessity of reconcentrating large quantities of diluted sulphuric acid to 95 to 97 per cent. It is reported that this difficulty has been overcome by the Compagnie de Béthune by neutralizing the diluted acid with ammonia and marketing the ammonium sulphate. So far as is known, the only firms actually manufacturing ethyl alcohol by this process are the Compagnie de Béthune and the Carbide and Carbon Chemicals Corporation.

SUMMARY

In the preceding discussion of the conversion of ethylene to alcohol by absorption in sulphuric acid and subsequent hydrolysis, the following salient features may be noted:

(1) The two principal reactions occurring during absorption are: first, the formation of ethylsulphuric acid, and second, at a later stage in the absorption operation, the production of diethyl sulphate.

$$C_2H_4 + H_2SO_4 \longrightarrow C_2H_5SO_4H$$
$$C_2H_4 + C_2H_5SO_4H \longrightarrow (C_2H_5)_2SO_4$$

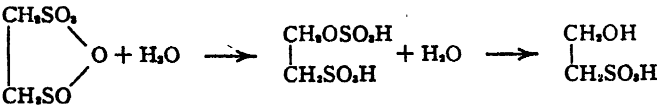
(2) The absorption of ethylene in sulphuric acid under ordinary conditions is rather slow but may be accelerated (a) by employing acid of very high concentration, (b) by increasing the reaction temperature, (c) by efficient agitation and intimate contact of acid with gas, (d) by adding such catalysts as silver sulphate or cuprous salts, and (e) by increasing the partial pressure of ethylene.

(3) The limiting concentration of acid is about 100 per cent or slightly less, since fuming acid favors the formation of carbyl sulphate, which hydrolyzes, not to alcohol, but to ethionic acid,[60] and then to isethionic acid, thus:

[59] Bataafsche Petroleum Maatschappij, British Patent 336,633, 1930; *Chem. Abs.*, 1931, **25**, 1843. Dutch Patent 27,237, 1932; *Chem. Abs.*, 1932, **26**, 5574; French Patent 695,707, 1930; *Chem. Abs.*, 1931, **25**, 2733; French Patent 696,561, 1930; *Chem. Abs.*, 1931, **25**, 2733.

[59a] Lloyd, Brown, Bonnell and Jones, *J.C.S.*, 1928, 658. See also Suknevitsch and Tschilingarian, *J. Gen. Chem. Russ.*, 1932, **2**, 783; *Brit. Chem. Abs.* **A**, 1933, 372.

[60] Salts of ester-like condensation products of ethionic and fatty acids have been suggested as detergents. Such materials are discussed in Chapter 46.



$$\begin{matrix} CH_2SO_2 \\ | \quad\; \diagdown \\ | \qquad O \\ | \quad\; \diagup \\ CH_2SO \end{matrix} + H_2O \longrightarrow \begin{matrix} CH_2OSO_3H \\ | \\ CH_2SO_3H \end{matrix} + H_2O \longrightarrow \begin{matrix} CH_2OH \\ | \\ CH_2SO_3H \end{matrix}$$

(4) An increase in the temperature of absorption causes a notable increase in the velocity of reaction. Here again there is a practical limit, which appears to be in the neighborhood of 100° C., beyond which undesirable side reactions occur.

(5) All observers have stressed the importance of intimate contact for a sufficient time between the acid and gas. The methods for achieving intimate contact vary widely and comprise the use of porous or granular packing material, mechanical agitation, countercurrent washing over Raschig rings or other extended surfaces, and the addition of foam- and froth-producing materials and emulsifying agents, as well as organic solvents.

(6) It has been demonstrated beyond doubt that certain catalytic materials and increased pressures both increase the velocity of absorption.

(7) The hydrolysis of ethylsulphuric acid seems to be fairly rapid in the presence of water at 100° C. and involves little difficulty. Ammonia has been proposed as a neutralizing agent. Depending upon the degree of dilution of the ethylsulphuric acid, hydrolysis and distillation yield alcohol or ether or mixtures of the two. Dilution with about an equal volume of water favors high proportions of alcohol in the product.

DIETHYL SULPHATE

It is interesting to note that diethyl sulphate may be used as a commercial ethylating reagent in many organic reactions. According to Cade,[61] it has a boiling point of 96° C. at 15 mm., of 120.5° C. at 45 mm., and of 208° C. at 760 mm. (with decomposition); d^{19}_{4} 1.837, and melting point of —24.5° C.; is non-inflammable and non-toxic. Organic hydroxy-compounds react readily with this material to yield ethers, while inorganic salts convert it to the corresponding esters. With amines, diethyl sulphate gives either mono- or di-substituted derivatives. Thus, diethylaniline is obtained by the action of 1.4 moles of diethyl sulphate on 1 mole of aniline in the presence of 1.2 moles of calcium hydroxide. Other procedures, than those previously mentioned, for the manufacture of diethyl sulphate involve the reaction between ethyl alcohol and sulphuric acid or sulphur trioxide,[62] and the vacuum distillation of ethylsulphuric acid.[63]

HIGHER ALCOHOLS FROM ETHYL ALCOHOL

The catalytic conversion of ethyl alcohol to alcohols of higher molecular weight, such as butyl alcohol, has been proposed. One process for such a conversion is the passage of ethyl alcohol vapors at superatmospheric pressure (130 atmospheres or higher) and at temperatures of about 325° C. over a catalyst of magnesium oxide containing a small proportion of copper oxide.[64] In another procedure,[65] ethyl alcohol vapors together with hydrogen are conducted at atmospheric pressure and a temperature of 200° C. or higher over a magnesium oxide catalyst activated by the oxides of metals such as lead, nickel, cobalt, silver, uranium, tungsten, copper and others. The catalyst may be stabilized by the addition of aluminum hydroxide, stannic acid, silica gel or wood charcoal. The products consist not only of n-butyl but also hexyl and octyl alcohols, acetaldehyde, and some butyric and crotonic aldehydes. By passing a mixture of ethyl and methyl alcohol and hydrogen over these catalysts a product is obtained containing methylethylcarbinol, propyl, isobutyl, butyl, hexyl, heptyl, octyl and nonyl alcohols.[66] Joshua, Stanley and Dymock[67] pass a mixture of ethyl and butyl alcohols and hydrogen over a mixed catalyst of aluminum, uranium, and thorium oxides with copper, silver, nickel or chromium. The main product is hexyl alcohol.

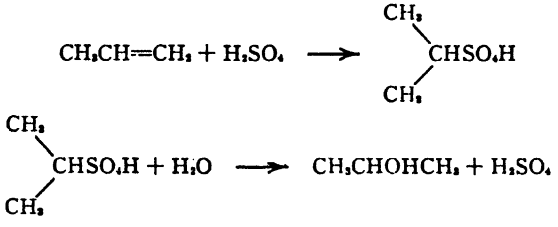
Chapter 14

Reaction Between Sulphuric Acid and Propylene. Production of Isopropyl Alcohol

The reaction between ethylene and concentrated sulphuric acid results almost exclusively in the esterification of ethylene with the production of ethylsulphuric acid and subsequently of diethyl sulphate. Propylene, however, reacts much more rapidly and easily with sulphuric acid and therefore less concentrated acid and lower temperatures may be employed. One can even separate ethylene and propylene by using sulphuric acid of the proper concentration. The simple esterification of propylene is complicated by polymerization and decomposition of the polymers as the predominating reactions at higher temperatures. Diluted acid is customarily used as concentrated acid favors the formation of polymers.

In the following pages a résumé is given of the most important work on the reactions of propylene and sulphuric acid, the subject being treated with special reference to the production of isopropyl alcohol. Since many of the industrial processes for making alcohols from olefins are concerned with mixtures of ethylene homologues found in the gas from cracking plants, some of the methods here given are also applicable to the production of the higher secondary and tertiary alcohols, a subject more fully discussed in a subsequent chapter.

It has long been known that propylene can be converted into isopropyl alcohol by reaction with sulphuric acid followed by hydrolysis of the resulting isopropylsulphuric acid, as follows:



$$CH_3CH{=}CH_2 + H_2SO_4 \longrightarrow (CH_3)_2CHSO_4H$$

$$(CH_3)_2CHSO_4H + H_2O \longrightarrow CH_3CHOHCH_3 + H_2SO_4$$

Yet the published work dealing with these reactions is not very extensive. Berthelot carried out some investigations on the production of secondary alcohols by this method. As early as 1855 we find his publications, one dealing with the absorption of propylene in sulphuric acid followed by the distillation of the acid compound mixed with water[1]; and others discussing the use of 98 per cent sulphuric acid[2] and the transformation of the alcohol, produced from olefin-containing gas and sulphuric acid, into ether.[3] Later Berthelot[4] investigated the velocity of and the effect of temperature on the absorption of propylene in sulphuric acid, and the formation of polymerization products during the subsequent distillation with water. He observed that sulphuric acid hydrate absorbed two hundred times its volume of propylene and that on mixing with water and distilling, an alcohol with a boiling point of 82° C. was obtained.

Plant and Sidgwick[5] noted that the rate of absorption of propylene in sulphuric acid was very much greater than that of ethylene. On passing propylene through 97 per cent sulphuric acid at 25° C., a 50 per cent increase in weight took place in two hours. Apart from the production of isopropylsulphuric acid and isopropyl sulphate there was also formed a quantity of colorless oil boiling from 55° to 155° C. at 30 mm. Analysis of this oil together with the fact that it appeared to react with metallic sodium led Plant and Sidgwick to believe it was a mixture of higher secondary alcohols produced by the action of sulphuric acid on the polymers of propylene. This conclusion, however, has been contested by Ormandy and Craven.[6]

A series of measurements of the relative rates of absorption of gaseous olefins in sulphuric acids of various concentrations has been reported by Davis and Schuler.[7] Their results for the absorption of ethylene in concentrated acid showed: (a) the film of acid on the glass walls of a pipette absorbed as much per unit area as the surface of the acid itself, (b) the absorption rate was not greatly changed by renewal of the surfaces or by the agitation in the liquid caused by rotation of the pipette, and (c) the rate was hardly affected by a nine-fold change in the volume of the acid. In view of these results Davis and Schuler concluded that the reaction between ethylene and sulphuric acid takes place entirely in a very thin film at the surface. These investigators showed that the absorption rate of propylene always remained about 300 times that of ethylene for acid concentrations of 80 per cent and higher, this in spite of the fact that the absolute values for the rates of absorption changed almost 200-fold over the range of acid concentrations employed.

Ormandy and Craven in a series of publications[8] have brought forward much evidence to show that the interaction of olefin hydrocarbons with sulphuric acid produces not only alcohols, alkylsulphuric esters, and olefin polymers, but a remarkable splitting of the olefin polymers takes place yielding considerable quantities of paraffin hydrocarbons. Empirically the reaction leading to the production of open chain paraffins is written by Ormandy and Craven as:

$$3xC_nH_{2n} \longrightarrow 2C_{nx}H_{2nx+2} + C_{nx}H_{2nx-4}$$

Thus it was found that on bubbling gaseous olefins, of 3 or more carbon atoms per molecule, through 98 per cent sulphuric acid at 25° C. separation of colorless oils occurred immediately. Dilution of the acid layer yielded oily products referred to as acid wash oils and the residual aqueous acid was fractionated to recover the free alcohols. The separated oils possessed physical properties and yielded analytical results which showed that they consisted of mixtures of open chain paraffins. The acid wash oils were unsaturated, had a high refractive index, and tended to darken on exposure to air. Apparently Ormandy and Craven considered that triolefins are present in these oils. Some results obtained with propylene are noteworthy. Propylene was passed into 98 per cent acid below 25° C. until about 12 per cent by weight was absorbed. The products of the reaction contained 46.7 parts of free oil, 44.7 parts of acid wash oils, and 5.2 parts of

[8] *J. Inst. Pet. Tech.*, 1927, **13**, 311, 844; *J.S.C.I.*, 1928, **47**, 317T; 1929, **48**, 293T.

isopropyl alcohol per 100 parts of olefin absorbed. The absorption of propylene was studied in some detail and the result established that one molecule of sulphuric acid absorbs at least three molecules of propylene over and above that which goes to form hydrocarbons. Thus by absorbing propylene in 98 per cent acid below 25° C. for 17 hours 1.10 moles of propylene (per mole of sulphuric acid) were recoverable as hydrocarbons and in addition 3.78 moles of propylene were otherwise absorbed. In an experiment in which propylene was absorbed in 80 per cent sulphuric acid, a 10 per cent increase in weight took place after 14 hours bubbling and 24 per cent of the propylene was converted into paraffins and 62 per cent into isopropyl alcohol. This experiment clearly confirmed the findings of Ellis and his co-workers as to the desirability of using as dilute acid as possible, consistent with sufficiently rapid absorption, to avoid undesirable side-reactions in the manufacture of isopropyl alcohol from propylene.

By saturating 98 per cent sulphuric acid with propylene at as low a temperature as the melting point of the mixture would permit, Ormandy and Craven[9] were able to prepare diisopropyl sulphate, a colorless liquid melting at —19° C., d^{15} 1.1155, and n^{16}_{D} 1.4121, which decomposes rapidly when warmed to 55°-60° C. This instability of diisopropyl sulphate was also noted by Bert,[10] who prepared the substance by the action of sulphuryl chloride on the sodium derivative of isopropyl alcohol. Medvedev and Alekseeva[11] found that on removing all traces of mineral acids the diisopropyl sulphate was quite stable. It could be distilled *in vacuo* without appreciable decomposition and kept unchanged for several days over calcium chloride.

Attempts have been made by a number of workers to hydrate propylene to isopropyl alcohol with water in the presence of catalysts. On passing a stream of propylene, to which a quantity of steam had been added at 125° to 130° C., countercurrent to a stream of 45 per cent sulphuric acid or of a concentrated aqueous solution of benzenesulphonic acid, Wibaut and Diekmann[12] obtained some isopropyl alcohol on cooling the exit gases. By carefully adjusting the proportion of steam in the ingoing gases it was possible to maintain the concentration of the acid at a constant value, and under these conditions the acid functioned as a hydrating catalyst. A large proportion of the propylene, however, was decomposed by the sulphuric acid and separation of carbon and formation of sulphur dioxide took place.

Comparatively few experimental details have been published on the conditions necessary for the production of good yields of isopropyl alcohol from propylene. The conclusion of Ormandy and Craven that it is difficult to prepare isopropyl alcohol by the use of sulphuric acid without losing 30 per cent or more by polymerization was contested by Norris and Davis,[13] who stated that carefully controlled tests both in the laboratory and in a semi-commercial plant have shown that it is possible to obtain almost quantitative yields of isopropyl alcohol from propylene using very concentrated sulphuric acid.

INDUSTRIAL PRODUCTION OF ISOPROPYL ALCOHOL

The production of tremendous volumes of gaseous and low-boiling liquid olefins during commercial cracking operations has greatly stimulated the industrial use of these olefins as raw materials for the manufacture of secondary and even of

[9] *J.S.C.I.*, 1930, 49, 362T; *cf.* Levaillant, *Compt. rend.*, 1929, 188, 261; *Chem. Abs.*, 1929, 23, 4669.

tertiary alcohols. The first commercial production of isopropyl alcohol was undertaken during the War period by the Melco Chemical Co. operating the Ellis process.[14] The still gases obtained in the cracking process were freed of hydrogen sulphide and water vapor, and the olefins then absorbed by passing the gases through 87 per cent sulphuric acid (sp. gr. 1.8) at 15° to 20° C., a rise in temperature being avoided by refrigeration. The undissolved gases at that time were used for fuel. When the specific gravity of the acid solution reached 1.4, the product was diluted with 4 volumes of water, and the polymers which separated were withdrawn. The diluted acid was next distilled, and the isopropyl alcohol obtained as a 20 per cent aqueous mixture. The crude product was further concentrated by distillation, yielding a constant-boiling mixture of isopropyl alcohol and water, containing 91.09 per cent alcohol by volume.

During the World War when acetone was in great demand for making airplane "dope", the Bureau of Aircraft Production took over the Melco plant and thoroughly studied the problem of making acetone from the isopropyl alcohol by catalytic oxidation in the presence of copper, or other metals, and by its dehydrogenation in contact with heated zinc, copper or brass. The enormous wartime need of acetone undoubtedly could have been satisfied in this manner had not the termination of the War soon thereafter eliminated the demand. Later the Standard Oil Co. of New Jersey obtained the rights to the Ellis process, and for many years has been producing both 91 per cent and anhydrous isopropyl alcohol in large quantities at its Bayway refinery.

Since that time the higher secondary and tertiary alcohols have been added to the list of commercial organic chemicals. By far the most important production of such alcohols has been that carried out under the auspices of the Standard Oil Co. of New Jersey, who later organized the Standard Alcohol Co. to continue this development.[15]

Ellis [16] has developed a process for producing alcohols from cracking gas which consists in bringing the gas in contact with sulphuric acid of 1.8 specific gravity at fairly low temperatures (below 20° C.) in the presence of a nonreactive liquid absorbent for the gases immiscible with sulphuric acid. This process results in the absorption of propylene and higher olefins. The resulting acid liquor, when it has reached a specific gravity of 1.3 to 1.4, is hydrolyzed with water to yield a mixture of isopropyl alcohol and higher alcohols. The acid liquor may also be used to make acetates or other esters of the secondary alcohols by reaction with the sodium salt of the appropriate aliphatic acid. The ethylene present in the cracking gas may afterwards be absorbed in more concentrated acid (100 per cent) at 60° to 70° C., also in the presence of a liquid diluent (for example, molten paraffin wax), to yield ethylsulphuric acid.

Two other processes for the manufacture of alcohols by sulphuric acid treatment of olefins have been developed by Ellis.[17] In the first, cracked gasoline boiling up to 110° C. is agitated for 3 hours with sulphuric acid of 1.8 specific gravity, the temperature being kept low by cooling. The mixture is then allowed to stand and the acid extract, separating as a bottom layer, is drawn off, diluted with water, and distilled with steam to yield a mixture of water-insoluble alcohols. About 25 per cent of these alcohols boil up to 115° C., 55 per cent from 115° to 150° C., and 20 per cent above 150° C. The upper layer of hydrocarbons may

FIG. 23.—General View of

be retreated with sulphuric acid to extract the residual olefins, leaving a mixture of saturated hydrocarbons only. The second process is concerned with the production of acid extract and alcohols from the gaseous products of cracking. By washing the cracking gas in an absorption tower, packed with contact material, with sulphuric acid of 1.8 specific gravity at a temperature below 40° C., there is obtained an acid liquor, the major portion of which consists of sulphated derivatives of olefins (mixture of alkylsulphuric acids) of more than two carbon atoms, predominantly derivatives of propylene. Since the extent of polymerization depends mainly on the time of exposure of the olefin to sulphuric acid, on the temperature, and on the concentration of the acid, too high temperatures and too concentrated acids are to be avoided. The sulphated material, as formed, should be immediately mixed with water to check any sulphonation or polymerization. The alcohols may be removed from the dilute acid by distillation with steam.

In order to avoid excessive polymerization of propylene caused by too high an acid concentration or temperature, Brooks and Cardarelli[17a] kept the partial pressure of propylene in excess of 50 pounds per square inch. Best results were obtained with the partial pressure in excess of 100 pounds per square inch with an acid concentration of 75 to 80 per cent and a temperature of 10° to 30° C., or with an acid concentration of 70 to 75 per cent and a temperature of 40° C.

In the absorption of propylene, and its homologues present in cracking gas, in sulphuric acid of 1.8 specific gravity at about 20° C., protracted contact between the gas and the acid, as previously noted, is undesirable.[18] Generally speaking 3 to 10 hours circulation of each batch of acid is sufficient, according to Ellis,[18] to give good yields of alcohol, while the passage of the gas for 24

Isopropyl Alcohol Plant.

to 48 hours through a single batch of acid is likely to yield little or no alcohol. Introduction of the gas normally is continued until the specific gravity of the acid liquor has fallen to 1.3 to 1.4.[19]

Ellis[20] also suggested adding sulphuric acid of about 1.8 specific gravity gradually to cracked petroleum containing both olefins and saturated liquid hydrocarbons, separating the acid layer by settling and then hydrolyzing it to yield alcohols. Before hydrolysis, the acid layer can be used for the treatment of additional olefin-containing material.

The use of an inert liquid, such as petroleum oil, agitated with the absorbing acid has been recommended by Mann and Williams.[21] Gaseous propylene is readily soluble in such a petroleum liquid and by employing it, better contact between the acid and propylene is secured. This procedure also reduces the polymerizing effect of the acid on propylene.

Mann[22] proposed the removal of small quantities of oil from isopropyl alcohol by bringing the liquid into intimate contact with sawdust. Lebo[23] suggested separating isopropyl alcohol from other admixed alcohols by adding a small quantity of benzene to the crude isopropyl alcohol before distilling. The benzene forms a low-boiling mixture with the isopropyl alcohol and this mixture can be separated subsequently into benzene and isopropyl alcohol by distillation. It has also been reported by Lebo[24] that isopropyl, butyl and amyl alcohols may be

[19] Incidentally it is proposed to increase the yield of olefin by thermally dehydrogenating the paraffin hydrocarbons (remaining after the first absorption) at 500°-700° C. under a pressure of 7 to 8 pounds less than atmospheric. The resulting olefins are absorbed in acid of sp. gr. 1.8 to yield isopropyl and higher alcohols.

freed from certain impurities, particularly sulphur compounds, by first digesting the crude product with less than 2 per cent by volume of 40° Bé. nitric acid, then neutralizing the acid with an alkali, and finally distilling the alcohol from the neutralized mixture.

In the Ramage[25] process the low-boiling fractions of cracked distillates, containing both olefins and aromatics, are treated with 60° to 66° Bé. sulphuric acid, cooling if necessary to prevent loss of volatile hydrocarbons. For example, a fraction of cracked gasoline, boiling between 70° and 95° C., is treated with 25 per cent by weight of 66° Bé. sulphuric acid with thorough agitation. After the addition of the acid is completed, a volume of water, equal to about 10 times the volume of acid, is added and the mixture then allowed to separate into two layers. An alkali, such as sodium carbonate, may be dissolved in the water. This alkali

neutralizes the acid and assists in the hydrolysis of the alkylsulphuric acid derivative formed. The upper, or oil layer, is withdrawn and separated into various fractions by distillation. The lower-boiling fractions are said to consist largely of alcoholic and aromatic bodies, the intermediate fractions of xylol and terpenes, and the high-boiling fraction (above 275° C.) is a lubricating oil, very probably containing largely polymerization products of the olefins.

In another process developed by Ramage[26] a mixture of olefin and aromatic hydrocarbons, having a boiling range of 20° to 150° C. obtained by the cracking of petroleum oil, is treated with about 20 per cent by volume of 66° Bé. sulphuric acid, the temperature being maintained below 40° C. Upon settling the mixture forms two layers: (1) a supernatant mixture of liquid hydrocarbons mostly of an aromatic nature (which can be fractionated and the lower fractions nitrated to yield nitro-compounds) and (2) an acid sludge, consisting of a mixture of sulphuric acid derivatives of the lighter olefins, chiefly those up to and including $C_{10}H_{20}$, and acid resins derived from the higher olefins. The acid sludge is diluted with an equal volume of water, agitated, and allowed to settle, yielding (1) an aqueous solution of various alcohols which is distilled to concentrate the alcohols, and (2) a tarry layer containing acid resins. The latter is extracted with 10 per cent caustic soda solution from which the acid resins may be precipitated by acidulation.

FIG. 25.—Steam Stills in an Isopropyl Alcohol Plant.

A process described by McElroy[27] is intended to convert the gaseous olefins present in oil gas into alcohols by what may be virtually a catalytic hydration in the presence of sulphuric acid. Olefin gas is brought into contact with sulphuric acid of such a concentration and at such a temperature that the olefin is absorbed and immediately given up in the form of alcohol, which is carried forward in the gas stream and condensed. The olefin gas first passes through a preliminary scrubber where it comes in contact with dilute sulphuric acid (1 part of acid and 3 parts of water) which removes the more easily polymerized olefins. The olefin gas then passes from the top of the preliminary scrubber to the base of the reaction chamber, which is maintained at a temperature of 80° to 100° C. by a heating packet. Dilute sulphuric acid is fed into the top of the reaction chamber and flows down through a customary bubble tower arrangement to secure intimate contact with the ascending stream of olefin gas. As the temperature of the reaction chamber is high enough to cause the evaporation of some water, the acid withdrawn from its base is much more concentrated than that entering the top. This concentrated acid, together with any dissolved olefins, is pumped back to the acid tank at the top of the reaction chamber, where it is diluted with water to the original strength. The olefin gas passing up through the chamber is absorbed by the acid, forming alkyl acid derivatives. These are immediately hydrolyzed to the corresponding alcohols, which in turn are vaporized. The alcohol vapors together with water vapor pass out of the top of the reaction chamber into an accessory column still. Part of the water vapor is condensed in a preliminary condenser and returned to the reaction chamber. The uncondensed gases are led to a final condenser to yield a condensate containing 10 to 15 per cent or more of alcohol, which may be further rectified.

[26] U. S. Patent 1,483,835, Feb. 12, 1924; *Chem. Abs.*, 1924, 18, 1194.
[27] U. S. Patent 1,438,123, Dec. 5, 1922; *Chem. Abs.*, 1923, 17, 771.

The Compagnie de Béthune[28] proposed the conversion of the ethylene homologues (principally propylene) present in coke-oven gas into the corresponding alcohols by treatment with about 90 per cent sulphuric acid at 18° C., followed by hydrolysis of the alkylsulphuric acid and distillation of the alcohols.

The successive removal of olefins in the gases from cracking operations is reported by Taveau.[29] The olefin-containing gases are passed countercurrent to sulphuric acid through a series of reaction chambers. By using acids of successively higher concentrations and by raising the temperature, the removal of the olefinic gases in stages is accomplished. For example, the cracking gases are first brought into contact with 65-66 per cent sulphuric acid at 30° C., under which conditions isobutylene is absorbed. The residual gases are next treated with 85 per cent acid, at the same temperature, which removes the remaining isomeric butylenes. Acid of about 94 per cent concentration, in the following series of reaction chambers at 30° C., reacts with the propylene, and 98 per cent acid at 100° C. used in the last chambers absorbs ethylene. The reactive acid liquor from each step is hydrolyzed, or otherwise treated, as soon as possible to avoid unnecessary polymerization.

Another process suggested for the separation of olefins from gaseous mixtures consists in treating the mixture with sulphuric acid in three stages.[30] The concentration of the acid for the first stage is less than 65 per cent, for the second stage, 78 to 82 per cent, and for the third stage, above 90 per cent. For the first two stages the temperature is kept at 32° to 49° C. The addition of an absorption oil to the acid assists by promoting more intimate contact between the acid and olefins and by reducing polymerization of the olefins.

The fractional extraction of olefins from cracking gas at lower temperatures, 3° C. or less, has been reported.[31] At such temperatures sulphuric acid of not less than 75 per cent strength removes isobutylene and the amylenes, while propylene and the normal butylenes are absorbed by acid of not less than 88 per cent strength.

An apparatus for the absorption of olefins present in petroleum distillation gases has been described by Mann.[32] The absorbing liquid may be, for example, sulphuric acid of 1.8 specific gravity mixed with a saturated paraffin oil in the

proportion of 1 part of acid to 5 parts of oil, and gas is supplied to the absorber under a pressure of 4 to 5 atmospheres.

A plan offered by Pilat, Piotrowsky and Winkler[33] to produce propyl and butyl, as well as higher, alcohols from the olefins of gases obtained in coal distillation or from the cracking of oil utilizes numerous features described above. The gases, after being desulphurized, dehydrated and freed of gasoline, are absorbed under pressure at temperatures below 20° C. in 70 to 90 per cent sulphuric acid. A well-refined oil, such as solar oil, may be mixed with the sulphuric acid.

Another procedure involves using dilute sulphuric or hydrochloric acids (concentration less than 3 moles per liter) at high temperatures and maintaining the gaseous olefins under high pressures.[34] For example, propylene or a higher olefin at a partial pressure greater than 10 atmospheres is forced into the dilute acid at a temperature of 150° to 222° C. Catalysts consisting of compounds of bismuth or of copper may be added to the acid. This method may be utilized also for the separation of propylene and higher olefins from ethylene. Apgar[35] suggested treating a gas containing unsaturated hydrocarbons (propylene and butylene) with 70 to 90 per cent sulphuric acid under 100 to 150 pounds pressure at 21° to 27° C. After treatment with the acid, the immiscible oils are separated, and the alcohols recovered from the acid extract by hydrolysis and distillation.

The Société Anonyme d'Explosifs et de Produits Chimiques[36] separated cracking gases by liquefaction into fractions consisting of (1) pentanes and amylenes and (2) butanes and butylenes. Propylene and ethylene remaining in the residual gases are treated with cold sulphuric acid in which the propylene is absorbed, the ethylene remaining undissolved. Hydrolysis of the acid products followed by distillation yields isopropyl alcohol. Higher secondary and tertiary alcohols may be obtained by treating the liquid olefin fractions in a similar manner.

The process of Curme and Reid[37] for the production of isopropyl alcohol calls for the absorption of propylene in concentrated sulphuric or phosphoric acids at a temperature of —10° to 0° C., the temperature rising to 15° to 20° C. toward the end of the absorption. The product, containing as much as 80 per cent of diisopropyl sulphate, is hydrolyzed by emulsifying with water below 40° C. and the alcohol recovered in the usual manner.

Merley[38] described an interesting process for the production of alcohols from olefins. He sought to produce alcohols in a very pure state by eliminating the evil-smelling polymers principally by hydrolyzing the acid solution with four volumes of water and then dissolving the polymers in alcohols, particularly those having more than five carbon atoms. These higher alcohols are either formed during hydrolysis of the acid sulphates of the corresponding olefins originally present, or they are added during the operation.

Merley treated the gaseous olefins in a reaction chamber countercurrently with sulphuric acid. The absorption mixture then enters a second reaction chamber where liquid olefins are introduced, the reaction temperature being kept between

0° and 5° C. The ester mixture is withdrawn to the acid settling tank where the hydrocarbons separate. From there the sulphuric ester mixture passes to the *drowning tank* where it is diluted with water, generally four volumes of water to one volume of the ester mixture, and cooled at the same time to prevent any rise in temperature. At this stage a large quantity of polymers separates and is decanted. The mixture is next conducted to a lead-lined hydrolysis tank, to which is attached a reflux condenser. Here, a heating appliance raises the temperature of the diluted mixture and hydrolysis occurs with the formation of alcohols. During heating and hydrolysis the temperature is kept low enough so that alcohol vapors are condensed by the reflux condenser. At the same time some of the polymer material, which had not previously separated, dissolves in the heavy alcohols having more than five carbon atoms. As stated above, if these alcohols are not formed from the olefins originally present they may be added in sufficient quantity before or after the dilution with water in order to dissolve the polymers and thus separate them from the other alcohols. Completion of hydrolysis is indicated when the surface layer temporarily changes in color from brown to green, which usually occurs after four hours of heating. The heating is immediately stopped and the resulting mixture of alcohols, water and acid quickly cooled. After cooling an additional quantity of the alcoholic solution of polymers rises to the surface and is withdrawn. The mixture of diluted acid and alcohol is then distilled in a lead-lined still and the following fractions are separated:

(1) Up to 80° C., consisting chiefly of ketones and some isopropyl alcohol.
(2) From 80° to 82° C., principally crude isopropyl alcohol of specific gravity 0.8166 to 0.8200.
(3) From 82° to 86° C., principally isopropyl alcohol together with some butyl alcohol, the mixture having a specific gravity of 0.82 to 0.848.
(4) From 86° to 88° C., crude butyl alcohol of specific gravity 0.848 to 0.863.
(5) From 88° to 100° C., containing the higher alcohols.

These fractions are further treated in the usual manner to obtain the various alcohols in a pure state.

A description of a method for the conversion of the olefins present in the gaseous and low-boiling products from cracking petroleum distillates in the vapor phase at about 610° to 620° C., into various secondary and tertiary alcohols has been given by Davis and Murray.[39] These olefins are first separated into several fractions, each of which is then further treated separately. It was determined by Davis and Murray that such olefins may be arranged in the order of increasing reactivity toward sulphuric and other polybasic acids [39a] shown in Table 82.

The initial separation of the olefins is effected as follows: The gases are first desulphurized and washed with cooled gas oil to dissolve the butylenes and higher olefins. The gas escaping from the scrubbers contains ethylene and propylene together with hydrogen and saturated hydrocarbons. The gas oil from the scrubbers passes into a still and on heating discharges its dissolved butylenes and amylenes (mixed with some paraffin hydrocarbons). By adjusting the temperature and pressure the amylenes are condensed and the butylenes pass on in gaseous form. This treatment results in the separation of the olefins from one another

[39] British Patent 248,375, 1926; *Brit. Chem. Abs.* B, 1927, 403. U. S. Patents 1,790,517 and 1,790,523, Jan. 27, 1931. French Patent 614,023, 1926. All patents assigned to Petroleum Chemical Corp. See also Little, *J.S.C.I.*, 1929, 48, 202T.

[39a] Ormandy and Craven (*J. Inst. Pet. Tech.*, 1931, 17, 185; *Chem. Abs.*, 1931, 25, 2841; see Chapter 50) also observed that with acid concentrations of 81 to 92.8 per cent. olefins of high molecular weight were more resistant to sulphuric acid than those of low molecular weight. This was not true with higher concentrations of acid, however.

TABLE 82.—*Olefins Arranged in Order of Reactivity Toward Sulphuric Acid.*

Olefin	Boiling Point ° C.	State
Ethylene	— 103	Gas
Propylene	— 48.5	Gas
Pentene-1	39–40	Liquid
Pentene-2	36 (741 mm.)	Liquid
Butene-1	— 5	Gas, or in solution
Butene-2	1	Gas, or in solution
Isopropylethylene	21.1	Liquid
Unsymmetrical methylethylethylene	31–33	Liquid
Trimethylethylene	37–42	Liquid
Isobutylene	— 6	Gas, or in solution

into the following fractions, each of which also contains paraffin hydrocarbons and certain highly unsaturated substances:

(1) The gaseous fractions containing ethylene and propylene.
(2) The butylene fraction containing isobutylene, butylene-1 and butylene-2.
(3) The residue of the condensate which may contain each of the five isomeric amylenes and varying amounts of hexenes and higher olefins.

The ethylene-propylene fraction [i.e., fraction (1)] is first scrubbed with 80 to 84 per cent sulphuric acid to remove the highly reactive hydrocarbons, after which the propylene is absorbed in 95 to 100 per cent sulphuric acid at a temperature below 30° C., leaving the ethylene virtually unattacked. Isopropyl alcohol is then obtained in the usual way by hydrolysis and distillation.[40] Fractions (2) and (3) will be referred to again in Chapter 16 in connection with the production of the higher secondary and tertiary alcohols.

The Bataafsche Petroleum Maatschappij[41] suggested the use of certain catalysts for the absorption of ethylene and its homologues in sulphuric acid. These catalysts, among which may be mentioned potassium ferrocyanide and ferricyanide and other complex cyanides such as sulphoferricyanic acid, sodium nitroprusside, sodium ferrocarbonyl-pentacyanide, are said to minimize polymerization reactions. The absorption of butene-1, for example, is said to be effected by heating 90 grams of the butene with 400 grams of 70 per cent sulphuric acid and 10 grams of potassium ferrocyanide for several hours in an autoclave. The yield of butyl alcohol is 80 per cent. Butyl acetate can be prepared directly by heating glacial acetic acid with a similar mixture for 8 hours at 80° C. in an autoclave. Propylene can also be absorbed to the extent of 90 per cent in a liquid prepared by passing carbon monoxide or nitric oxide through a suspension of cuprous oxide (5 grams) in 90 per cent sulphuric acid (100 cc.).[41a] The isopropyl alcohol resulting on hydrolysis can be dehydrated with anhydrous potassium carbonate, calcium oxide, calcium chloride, or better, copper sulphate.[41b]

The direct esterification of propylene by a mixture of an organic acid and sulphuric acid was described by Woolcock.[42] Equal volumes of 99.5 per cent sulphuric acid and glacial acetic acid are treated with propylene at 40° C. until no more gas is absorbed. On diluting with water isopropyl acetate separates and from the diluted acid layer isopropyl alcohol can be recovered. Of the propylene absorbed 53 per cent appeared as isopropyl alcohol and 27 per cent as isopropyl acetate, while in a comparative experiment, using 99 per cent sulphuric acid alone, the yield of isopropyl alcohol was only 5 per cent, because of polymerization. In another example, oil gas containing 28 per cent propylene, 30 per cent ethylene and the remainder hydrogen and paraffin hydrocarbons was passed into a mixture of equal volumes of 99.5 per cent sulphuric acid and glacial acetic acid at a temperature of 40° C. The exit gas contained only 5 per cent propylene, and isopropyl alcohol and isopropyl acetate were recovered as before from the acid mixture.

Chapter 15

Properties and Uses of Isopropyl Alcohol and Its Derivatives

Isopropyl alcohol has been produced in commercial quantities since about 1919, first by the Melco Chemical Co. and then by Standard Oil Co. of New Jersey, from the propylene of cracking gas. Since 1932 it has been manufactured by the Standard Alcohol Co., operating the Ellis process and including certain improvements of Davis and others. The industrial manufacture of this synthetic organic chemical is the direct result of the scientific exploration of petroleum as a chemical raw material. Although limited quantities of isopropyl alcohol have been manufactured in Europe by the hydrogenation of acetone, the production of this substance from the propylene of petroleum cracking has greatly reduced its cost and opened up a wide field of utility for both the alcohol and its many derivatives.

The production of isopropyl alcohol from the propylene of cracking gas amounted to about 37,500 gallons in 1922. In 1931, the production increased to about 1,500,000 gallons. It is now available in tank car lots at a price which makes it an economical solvent possessing advantages of great industrial significance.

The crude alcohol, resulting from the distillation of the dilute acid liquor, consists of isopropyl alcohol mixed with much water and small amounts of propyl ether, olefins and hydrocarbons. The crude alcohol stock may be purified by treating with alkaline calcium hypochlorite, alkaline potassium permanganate, silica gel or absorbent charcoal, followed by dehydrating with solid caustic soda, and finally fractionating. Usually, distillation of the aqueous alcohol is carried out to yield a constant-boiling mixture containing 91 per cent isopropyl alcohol and 9 per cent water. This azeotropic mixture is much more readily dehydrated than the corresponding ethyl alcohol azeotrope; a short digestion with an excess of dry solid caustic soda, followed by distillation, is sufficient to yield an anhydrous alcohol boiling at 82.4° C.[1]

The purification and deodorization of isopropyl alcohol is effected, according to Mann,[2] by the use of chlorine and decolorizing carbon. Agitation of the alcohol with a mixture of calcium hypochlorite and hydrochloric acid is suggested by Hudson[3] for the same purpose. Another process of purifying alcohols derived from olefins, proposed by Buc,[4] consists in agitating the alcohol with a highly refined petroleum distillate having an initial boiling point of 299° to 304° C., stratifying, separating and repeating the process six to eight times. The alcohol is then distilled. A method for extracting the polymers present in the crude alcohol or dilute acid liquor by a water-insoluble straight-chain mineral oil fraction [of which the initial boiling point is not less than 204° C. (400° F.)] has been described by Merley.[5]

---

[1] Grant and Johns, *Amer. J. Pharm.*, 1922, 94, 418.

[2] U. S. Patent 1,502,149, July 22, 1924; *Chem. Abs.*, 1924, 18, 2901; assigned to Standard Oil Development Co.

[3] U. S. Patent 1,657,505, Jan. 31, 1928; *Brit. Chem. Abs.* B, 1928, 255; assigned to Standard Oil Development Co.

[4] U. S. Patent 1,712,475, May 7, 1929; *Brit. Chem. Abs.* B, 1929, 886; assigned to Standard Oil Development Co. In a later process for purifying alcohols, Buc (U. S. Patent 1,911,798, May 30, 1933) eliminates tertiary alcohols and analogous impurities with an acid of high boiling point.

Isham[6] employed benzenesulphonic acid for the separation of alcohols, such as those formed from mixed olefins, and dissolved polymers. The polymers are difficultly soluble in benzenesulphonic acid which readily extracts the alcohols. Lyons[7] distilled the crude alcohol with sufficient water to throw the hydrocarbon impurities out of solution in the alcohol. The low-boiling impurities are first distilled from the diluted liquid, and these are followed by a fraction of practically pure alcohol which can be collected separately.

PROPERTIES OF ISOPROPYL ALCOHOL

Pure isopropyl alcohol is a colorless liquid with a somewhat bitter taste and characteristic, though not unpleasant, alcoholic odor. It is miscible in all proportions with water but may be salted out of solution by saturating with sodium chloride or other salts.

The ternary systems, water-isopropyl alcohol-salts, have been studied quantitatively at 25° C. by Ginnings and Chen[8] for ten inorganic salts and qualitatively for a large number of others. Of all the salts investigated, potassium carbonate and potassium fluoride exhibited the greatest salting-out effect. These investigators further reported that isopropyl alcohol was easier to salt out than methyl or ethyl alcohol, but more difficult than either n-propyl alcohol or tertiary butyl alcohol.

The anhydrous alcohol may be prepared by treating the 91 per cent alcohol with 10 per cent of its weight of flake sodium hydroxide, withdrawing the aqueous layer formed, again treating with a small proportion of sodium hydroxide, decanting the alcohol layer, and distilling.[9] The alcohol so produced can be mixed with eight volumes of carbon disulphide, xylene, or petroleum ether without showing any trace of turbidity.

The addition of dry sodium chloride to dilute alcohol results in the formation of two liquid layers. The lower layer is an aqueous solution of sodium chloride, while the upper layer is 87 per cent isopropyl alcohol containing about 2 to 3 per cent sodium chloride. Distillation of the upper layer yields isopropyl alcohol of practically the same composition as the 91 per cent azeotropic mixture.

The boiling point of the anhydrous alcohol at atmospheric pressure is given variously[10] by a number of observers but the figure 82.4° C. may be taken as most reliable. Several workers have recorded specific gravities, all at 15° C./15° C., for anhydrous isopropyl alcohol with more or less variance as follows:

Observer	d_{15}^{15}
Thorpe[11]	0.7903
Doroshewski[12]	0.7898
Young[13]	0.7899

Lebo obtained the value of d^{20}_4 as 0.7855 and found that the change in density per degree Centigrade was equal to 0.00080.

The vapor pressure of isopropyl alcohol of about 99.97 per cent purity was measured by Parks and Barton[15] with the results given in Table 83.

TABLE 83.—*Vapor Pressure Data for Isopropyl Alcohol.*

Temp. ° C.	Vapor Pressure Mm. Hg.	Temp. ° C.	Vapor Pressure Mm. Hg.
0.00	8.9	50.00	176.8
5.00	12.1	55.00	227.4
10.00	17.0	60.00	288.5
15.00	23.8	65.00	363.1
20.00	32.4	70.00	454.8
25.00	44.0	75.00	561.4
30.00	59.1	80.00	691.8
35.00	78.9	85.00	845.6
40.00	105.6	90.00	1020.7
45.00	136.8		

From the above data the molal heats of vaporization in calories were calculated to be 10,620 at 25° C., 10,490 at 50° C., and 9,600 at 82.28° C., and the molal entropy of vaporization is 33.8 calories per °C. at 38.7° C. The most reliable value of the heat of vaporization at 82.2° C. is 161.0 ± 1.5 calories per gram.[16]

Solid isopropyl alcohol melts at 184.67° K. (—88.46° C.) and the heat of fusion is 1284 calories per mole (21.4 calories per gram).[17]

According to Richardson and Sutton,[18] isopropyl alcohol has a flash point of 12° C. and a lower explosive limit, in air at 25° C., of 2.5 per cent by volume. Its auto-ignition temperature in air varies from about 457° C. in pyrex glass to 649° C., 634° C. and 638° C. in the presence of copper, steel, and chromium, respectively.[19]

The specific gravity (d^{20}_4) of isopropyl alcohol-water mixtures are given by Lebo[20] in Table 84.

TABLE 84.—*Specific Gravity of Isopropyl Alcohol-Water Mixtures.*

Alcohol by Weight Per Cent	d^{20}_4	Alcohol by Weight Per Cent	d^{20}_4
100.00	0.78556	53.07	0.89868
90.35	0.80866	43.02	0.92418
85.09	0.82282	33.17	0.94590
74.35	0.84828	21.39	0.96847
65.22	0.87003	9.58	0.98293

Young[21] found that the boiling point of the azeotropic mixture of isopropyl alcohol and water is 80.37° C., and it consists of 87.90 per cent of weight of alcohol. Mixtures containing more alcohol than this azeotropic mixture, on boiling, evolve a vapor richer in alcohol than the liquid, and those with a lower alcohol content give off, on boiling, a vapor poorer in alcohol than the liquid, the composition of the vapor tending to approach that of the constant-boiling mixture. Lebo investigated the boiling points of various isopropyl alcohol-water mixtures and found that the azeotrope has a boiling point of 80.4° C., a composition of 87.7 per cent alcohol by weight (or 91.1 per cent by volume) and a density (d^{20}_4) of 0.8158.

The critical temperature of isopropyl alcohol is 234.9° C., according to Pawlewsky.[22]

Isopropyl alcohol contains one hydrogen atom replaceable by metals to form isopropoxides and double compounds of this alcohol and calcium chloride and other inorganic salts are known. In chemical properties, isopropyl alcohol is a typical secondary alcohol yielding well-defined esters and ethers and being oxidized readily to acetone, the corresponding ketone.

USES OF ISOPROPYL ALCOHOL

Isopropyl alcohol is finding increasing application in industry and the arts, notably as a solvent, dehydrating agent, and preservative, in the preparation of medicinal extracts, in the manufacture of perfumes,[23] cosmetics, astringents,[24] shampoos,[25] and theater sprays, and as a resin solvent. Smith and Eoff [25a] suggest its use in flavoring extracts. Briefly, it is being used more and more as a substitute for ethyl alcohol, mainly because isopropyl alcohol is not subject to trade restrictions, as is ethyl alcohol. Isopropyl alcohol, since it is not taxed and is readily available, can be sold at a lower price than even tax-free ethyl alcohol, hence it is in a position to compete with ethyl alcohol for every use.

PHARMACOLOGY OF ISOPROPYL ALCOHOL

Some doubts have been raised from time to time as to whether the substitution of isopropyl for ethyl alcohol, particularly in perfumery and in the manufacture of cosmetics and mouth washes, is entirely free from objections from the point of view of public health. The following summarizes the principal results of pharmacological and toxicological investigations of isopropyl alcohol to date.

Macht [26] found that when injected intravenously into cats, isopropyl alcohol is twice as toxic as ethyl alcohol, four-fifths as toxic as normal propyl alcohol, and one-fourth as toxic as benzyl alcohol. This relative order of toxicity was substantiated by comparative experiments on the action of various alcohols on the isolated hearts of frogs, and on isolated plain muscle. When rats were exposed to air saturated with the vapor of various alcohols, methyl alcohol killed them in one or two days, whereas several days' exposure to the vapors of either ethyl or isopropyl alcohols produced no apparent injury. Furthermore, no subsequent blindness or defects of vision resulted from the inhalation of isopropyl alcohol vapor.

According to experiments of Burton-Opitz [27] the application of isopropyl alcohol to wounds in concentrations up to 50 per cent resulted in healing, apparently by normal granulation. Isopropyl was found to possess healing properties

[27] Unpublished communication, quoted by Grant and Johns, *Amer. J. Pharm.*, 1922, 94, 418; *Chem. Abs.*, 1922, 16, 2944.

similar to those of ethyl alcohol, so far as these could be tested in dogs. When injected in small quantities and in concentrations of 10 to 100 per cent into the jugular vein and conjunctiva, the effect of isopropyl alcohol was approximately the same as that of ethyl alcohol.

Grant and Johns [28] reported that the use of isopropyl alcohol in lotions, liniments, antiseptic solutions for the throat, and in cleansing liquids, produced no noticeable injurious effects even after prolonged use. One of these investigators repeatedly took sponge baths from head to foot in 50 per cent isopropyl alcohol without injury.

An important detailed study of the physiological effects of isopropyl alcohol on rabbits, guinea pigs, dogs, cats, monkeys, and persons, by Fuller,[29] showed that when taken into the system in strength capable of being ingested without local discomfort, the animal economy is capable of absorbing this alcohol in reasonable amounts without toxic results. A form of intoxication is apparent, especially in the early part of the test, but a tolerance is quickly established and thereafter the outward appearance of intoxication differs in no respect from that induced by ethyl alcohol.

According to the observations of Munch and Schwartze,[30] the toxicity and the narcotic action of the alcohols of a homologous series increases with the molecular weight. A similar conclusion was also reached by Rost and Braun,[31] who found, however, that normal propyl alcohol is more active than isopropyl alcohol. It appears from the work of Kemal [32] that when isopropyl alcohol is administered to man it is excreted partly as acetone in the urine and in the breath; the amount of acetone excreted is greatly increased by drinking large amounts of water.

Bijlsma [33] critically examined the pharmacology of isopropyl alcohol with special reference to the question of its substitution for ethyl alcohol in cosmetics and mouth washes. Both alcohols have qualitatively the same effect on man and animals but quantitatively isopropyl is 2.4 times stronger than ethyl alcohol in the same molar concentration. The effect of drops in the eyes was the same for both alcohols. Local and general toxic effects were similar, the latter being quantitatively somewhat greater with isopropyl alcohol. Bijlsma concluded that the use of isopropyl alcohol in mouth washes and for external application need cause no concern.

In addition to the above, various opinions have been expressed regarding the use of isopropyl alcohol in the manufacture of cosmetics and toilet preparations. This alcohol exerts a definite disinfecting and preserving action and it has been used with success in the preservation of anatomical specimens.[34] Westermann [34a] found that the disinfecting value of aliphatic alcohols increases with their molecular weights. Boruttau [35] stated that there is no objection to the incorporation of isopropyl alcohol in cosmetics and toilet preparations,[36] and asserted that it can be safely used as a preservative in foods.[37]

The Federal Board of Health of the German Republic on May 18, 1926, submitted (to the Minister of the Interior) the following opinion[88] regarding the use of isopropyl alcohol in medicines, cosmetics, foods, and other preparations. "According to the relatively meager toxicological researches on isopropyl alcohols, it can only be stated that in animal experiments, it possesses a higher narcotic effect than does ethyl alcohol. Since experiments regarding the effect of this higher alcohol on human beings and its fate in the animal and human body are scarcely available, it is impossible to decide whether or not the use of isopropyl alcohol instead of ethyl alcohol should be permitted. Even if it should be found that isopropyl alcohol is not more harmful to human beings than is ethyl alcohol—which is contrary to results of animal experiments—the introduction of this alcohol which is pharmacologically more active and certainly not less harmful than ethyl alcohol, should be opposed for the protection of public health." This Board consequently forbade the use of isopropyl alcohol in medicines and foodstuffs but failed to discover any well-founded objections from a sanitary standpoint against its use in the preparation of odorants, perfumes and the usual cosmetic preparations.

Later, in a session held on March 22, 1929, the Federal Board of Health of the German Republic adopted the following view regarding the use of isopropyl alcohol.[89] "Isopropyl alcohol offers no advantage over ethyl alcohol, either physiologically or pharmacologically, which can be advanced as reason for its use instead of ethyl alcohol. From the sanitary point of view, however, no objections can be raised against its use for perfumes, odorants, cosmetics, such as mouth and tooth washes, nail polishes, brilliantines, hair washes, bay rum and massage preparations—except French brandy, and as hand disinfectant. Isopropyl alcohol must, however, be excluded from general use in medicines, including French brandy, for internal as well as external use, and also in foodstuffs."

To summarize, it may definitely be concluded that the substitution of isopropyl alcohol for ethyl alcohol in certain of its uses, particularly in preparations which are applied externally, is entirely free from objection.

SOLVENT PROPERTIES OF ISOPROPYL ALCOHOL

Isopropyl alcohol has proved superior to ethyl alcohol in solvent properties for some uses, though there is often a striking difference between the solvent powers of the 91 per cent isopropyl alcohol-water azeotrope and the anhydrous alcohol. Applications of this alcohol as a solvent include the following:[40]

(1) *In the manufacture of fine organic chemicals and synthetic materials, for extracting pure substances from mixtures or for extracting impurities from insoluble substances, and as a recrystallizing solvent.* Isopropyl alcohol may advantageously be used in the preparation or purification of benzoic acid, salicylic acid, β-naphthol, saccharin, acetanilide, benzaldehyde, salol, benzidine, creosote carbonate, veronal, benzonaphthol, various dyes, heliotropin, santonin, aloin, tannin, coumarin, saponins, hydroquinone, alkaloids generally, and others.

(2) *In the preparation of solid medicinal extracts, plant principles and oleoresins.* Although official preparations must be extracted by ethyl alcohol or acetone, as the case may be, there is a large field for the use of isopropyl alcohol for non-official products of this nature, for example, in proprietary remedies and

[88] *Reichs-Gesundheitsblatt,* 1926, 1, 810.

[89] *Reichs-Gesundheitsblatt,* 1929, 4, 549.

[40] For a review of the applications of isopropyl alcohol see, Grant and Johns, *Amer. J. Pharm.*, 1922, 94, 418; Valli-Donau, *Rev. parfumerie,* 1924, 4, 288.

flavoring compounds.[41] For the manufacture of such products isopropyl has important advantages over denatured grain alcohol on account of its purity and, where its solvent power is comparable with that of ether or acetone, it may replace these solvents advantageously with reduced fire hazard and diminished losses by evaporation.

(3) *As a solvent for medicinal substances for external medication.* The use of isopropyl alcohol in external medications should obviate the necessity for using poisonous or offensive denatured alcohol, expensive medicated alcohol and the rather costly pure ethyl alcohol. It should also be of value in the compounding of liniments, collodions, alcoholic lotions and antiseptic varnishes for burns. Ellis[41a] described the topical use of isopropyl alcohol in such preparations as witch-hazel extract and perfumes and as a rubbing alcohol in place of ordinary ethyl alcohol. The results obtained by Brandrup[42] indicated that this alcohol could be used advantageously in preparation of extracts of belladonna and cinchona. Despite its somewhat unpleasant taste, isopropyl alcohol can be incorporated in certain types of antiseptics for oral and nasal use and its solutions may be used for medicating surgical dressings.

(4) *In cosmetics.* The application of isopropyl alcohol as a solvent medium for the manufacture of perfumes, toilet waters, bay rum, hair tonics, bandolines, brilliantines, shampoo liquid or jelly, liquid rouge, and all kinds of cosmetic lotions, as well as in theater sprays is extensive.[43]

In the preparation of certain perfumes and barbers' specialties the odor of isopropyl alcohol has severely limited its application. In order to modify the odor and make it resemble that of ethyl alcohol more closely, Isham[44] proposed a solvent consisting of isopropyl alcohol, acetaldehyde, and butyl acetate in the proportion of 5 gallons of the alcohol, 3 cc. of acetaldehyde, and 6 cc. of butyl acetate.

(5) *In the laboratory.* Isopropyl alcohol is a useful solvent in the laboratory and may be employed for making solutions of phenolphthalein, methyl-orange, phloroglucinol, dimethylglyoxime and picric acid, as well as for standard soap solutions for water testing. It may be used in solvent extractions from aqueous solutions or from petroleum ether solutions. Miscibility is prevented, in the first case, by the addition of salts or alkalies to the water layer, and in the latter instance by adding water to the alcohol. Isopropyl alcohol can be employed in the preparation of staining solutions for bacteriological and pathological work. Its value in dehydrating tissues and in the preservation of biological specimens is already established. A number of tests carried out by Pope[45] on the preservation of newts gave favorable results with isopropyl alcohol solutions (aqueous) in concentrations of 40 to 50 per cent. Isopropyl alcohol competes in price with ethyl alcohol without the restrictions of the latter and is without the irritating properties of formaldehyde.

In connection with the use of isopropyl alcohol in pharmaceutical laboratories, Schamelhout[46] reports that it may be substituted for ethyl alcohol in the determination of acid numbers and saponification values of fats,[47] oils, and balsams, and also in such tests as the detection of rhapontic in rhubarb.

[45] *Science*, 1928, **68**, 487.

[46] *J. Pharm. Belge*, 1927, **9**, 401; *Chem. Abs.*, 1928, **22**, 1211.

[47] For the solubility of some vegetable oils in isopropyl alcohol of different concentrations see Hashi, *J. Soc. Chem. Ind. (Japan)*, 1931, **34**, 104B; 105B, 224B, 226B; *Chem. Abs.*, 1931, **25**. 3504; *Brit. Chem. Abs.* **B**, 1931, 894.

(6) *In the cellulose nitrate and cellulose acetate industries.* Although isopropyl alcohol is not a solvent for cellulose esters it has distinct latent solvent properties. Blending this alcohol with an ester, for example, yields a solvent for cellulose nitrate. Thus, Clough and Johns [48] propose a mixture of 47.5 per cent isopropyl acetate and 52.5 per cent isopropyl alcohol (azeotropic mixture, boiling at 80.1° C.) as a solvent for cellulose nitrate in the production of varnishes and films.

Isopropyl alcohol may serve as a solvent for camphor or camphor substitutes, in the preparation of plastics, "dopes," lacquers, films, and collodion.

(7) *As a resin solvent.* Isopropyl alcohol is a solvent for sandarac, mastic resins, common rosin and "bush kauri," and is a useful partial solvent for elemi, copal, and dammar. Isopropyl alcohol alone is not a good solvent for shellac. However, by adding a sufficient amount of methyl alcohol to the isopropyl alcohol, the shellac can be dissolved satisfactorily. Hudson [49] suggested employing a solution of a spirit-soluble gum, such as shellac, in 2 to 2.3 times its weight of isopropyl alcohol, as a glazing material for candy.

(8) *Miscellaneous.* Other applications of isopropyl alcohol as a solvent are in the production of wood stains and special dyeing materials, in the extraction of glycerol from distillery residues, in varnish and paint removers, in liquid soaps,[50] in disinfectant and deodorant solutions and insecticides, in dry cleaning preparations and, when mixed with hydrocarbons such as gasoline, as a paint or varnish thinner, degreasing agent, and motor fuel.[51] It has been proposed also as a solvent for the extraction of sulphonated compounds formed during the acid treatment of petroleum oils which are to be used for medicinal purposes.[52] Robinson [53] used isopropyl alcohol of at least 80 per cent concentration to revivify the spent fuller's earth from petroleum oil filtration operations. The extraction of lubricating oil from an asphalt-base residuum with this alcohol has been recommended by Taveau.[54]

After the vapor-phase oxidation of petroleum oils and removal of the lower boiling fractions (up to 300° C.), oxidation products may be extracted from the residue with 90 per cent isopropyl alcohol.[55] Dilution of the alcohol layer with water causes the separation of bodies which it is reported may be used as plasticizers for lacquers.

OTHER APPLICATIONS OF ISOPROPYL ALCOHOL

Anhydrous isopropyl alcohol proves a useful dehydrating agent in chemical, biological and photographic work, and may be used for drying nitrocellulose, sugars, starches, proteins, gelatin, and animal and vegetable tissues, for dehydrating histological specimens, and for cleaning and drying photographic prints and films. It can readily be recovered in an anhydrous state.

[55] James, U. S. Patent 1,835,600, Dec. 8, 1931; *Brit. Chem. Abs.* **B**, 1932, 877.

This alcohol may also be employed as a precipitant for proteins and peptones, for pepsin, trypsin, pancreatin, rennin, papain and other enzymes, as well as for various gums, sugars, soluble starches, silver protein compounds, and glycerophosphates.

Isopropyl alcohol is finding important application as a "key denaturant" for ethyl alcohol in various formulas for specially denatured alcohol to be used in the manufacture of perfumes and barbers' requisites.[56] Other important and likely applications of this versatile material are as an antidote for phenol burns, as a filler for thermometers, thermostats, and compasses, and in the preparation of anti-freeze liquids for automobile radiators.

ISOPROPYL ALCOHOL AS A CHEMICAL INTERMEDIATE

The availability of large supplies of isopropyl alcohol has opened up a wide field of possibilities in the commercial production of its derivatives. Already many of the esters of this alcohol are finding application as solvents or in perfumery and confectionery. Isopropyl ether is also attracting attention. Acetone can readily be produced from isopropyl alcohol (see Chapter 18). The isopropyl group may be introduced into organic compounds by means of isopropyl alcohol, thus making possible the production of a multitude of comparatively rare substances, some of which (e.g., thymol) find important industrial applications. Isopropylaniline and its homologues have been suggested as intermediates for the manufacture of dyes.[57] The product obtained on condensing a mixture of benzoin and isopropyl alcohol with naphthalene-β-sulphonic acid in the presence of sulphuric acid is said to be a distributing agent for insoluble substances.[58]

DETECTION AND ESTIMATION OF ISOPROPYL ALCOHOL

Methods for the detection and determination of isopropyl alcohol generally depend upon the oxidation of this alcohol to acetone, which is then recognized by the well-known nitroprusside test or otherwise. Other methods which have been proposed depend upon the reactions of this alcohol with piperonal and mercuric sulphate.

Rae[59] has suggested the following procedure for detecting isopropyl alcohol in wines and other liquors: Into a 200 cc. flask, place 20 cc. of a 1 per cent aqueous solution of potassium dichromate, 1 cc. of concentrated sulphuric acid and 10 cc. of the sample to be tested. The contents of the flask are distilled over a small flame using a bent glass tube as a condenser, and about 3 cc. of distillate is collected. The distillate is now carefully poured onto the surface of a solution consisting of 2 cc. of a 5 per cent sodium nitroprusside solution mixed with an equal volume of ammonia solution (sp. gr. 0.880) in a test tube to which about 2 grams of ammonium chloride has been added. The test tube is then set aside for a few minutes. If acetone, produced by the oxidation of isopropyl alcohol, is present a purple ring will appear at the junction of the two liquids. Rectified spirit gives a negative test by this method although methylated spirit reacts positively because of the presence of traces of acetone in the original. The reaction is stated to be sensitive to 0.1 cc. of isopropyl alcohol. A somewhat similar method, described by Henville,[60] is also sensitive enough to detect the presence of 0.1 per cent of isopropyl alcohol in wines.

---

[56] For use of isopropyl alcohol as a denaturant for ethyl alcohol, see Guinot, *Z. Unters. Lebensm.*, 1931, 62, 330; *Brit. Chem. Abs.* **B**, 1932, 42. In 1931 the U. S. Government, as well as several foreign governments, adopted isopropyl alcohol as a denaturant. The present U.S.C.D.5 formula contains 5 volumes of isopropyl alcohol to every 100 volumes of ethyl alcohol, and formulas C.D.5A and C.D.10 each contain 2½ volumes to every 100 volumes of ethyl alcohol. Isopropyl alcohol is also used in several special formulas.

[57] Buc, U. S. Patent 1,555,451, Sept. 29, 1925; assigned to Standard Oil Development Co. Isopropyl-p-aminophenol, from isopropyl chloride and p-aminophenol, may be used in the dyeing of furs or in photographic developers: Buc, U. S. Patent 1,555,452, Sept. 29, 1925; assigned to Standard Oil Development Co.

[59] *Pharm. J.*, 1926, **116**, 630; *Chem. Abs.*, 1926, **20**, 3665.

According to Noetzel[61] the presence of isopropyl alcohol in ethyl alcohol produces but little change in density and boiling point but appreciably raises its refractive index. The use of indices of refraction as criteria is impractical with wines on account of the disturbing influence of acids and esters. Oxidation to acetone gives the best method of detecting isopropyl alcohol and the process may be made quantitative by determining the acetone produced, e.g., by combination with hydroxylamine hydrochloride and subsequent titration of the free acid produced.

The detection of isopropyl alcohol in brandy by oxidation to acetone, which is then recognized by Griebels' microbeaker method using m-nitrophenylhydrazine, has been described by Weiss.[62] An excellent method of detecting isopropyl alcohol in spirits, tinctures, still wine and cosmetics is that of Reif[63] and depends upon the production of a red or reddish-brown color when a mixture of sulphuric acid, isopropyl alcohol and piperonal (or anisaldehyde) is warmed on the water-bath for a few moments. By this method it is claimed that 1 per cent of isopropyl alcohol can be detected without first destroying the aldehydes, terpenes, and acetals present in the mixture. It may also be extended to the detection of isobutyl alcohol.

The detection of isopropyl alcohol by the formation of a precipitate with mercuric sulphate, as proposed by Stainer and Lauwaet,[64] has been criticized by Matthes and Schütz[65] as not sufficiently specific since this reagent also yields precipitates with unsaturated hydrocarbons and tertiary alcohols.

Nearly all the available methods for the quantitative determination of isopropyl alcohol utilize its oxidation to acetone as the first step, after which the acetone is determined quantitatively by one of several methods. One of the best methods of determining the acetone produced is that of Bennett.[66] This consists in treating the acetone with hydroxylamine hydrochloride (with which acetone reacts yielding acetoxime and hydrochloric acid), followed by titration of the liberated acid with a standard alkaline solution. This method has been recommended by a number of workers, notably by Simmons,[67] who has tested its accuracy. Noetzel[68] gives the following method for the determination of isopropyl alcohol in wines or alcohol: The sample of wine or alcohol is diluted with water until 100 cc. contain not more than 5 cc. of isopropyl alcohol. Twenty-five cc. of this solution is mixed with 50 cc. of a potassium dichromate solution (98 grams per liter), 100 cc. of 50 per cent sulphuric acid is added, and the mixture cooled. After standing for 3 hours at room temperature the unchanged chromic acid is reduced by adding 100 cc. of 25 per cent ferrous sulphate solution and the mixture is steam distilled. Seventy-five cc. of the distillate is collected in a vessel containing 5 cc. of 10 per cent caustic soda solution and 10 cc. of water. This distillate is redistilled, about 50 cc. being collected in a receiver containing 2 grams of hydroxylamine hydrochloride in 20 cc. of water. After shaking the latter mixture for 1 hour, the free hydrochloric acid is titrated with 0.25*N* caustic soda solution using methyl-orange as an indicator. As a blank, the hydroxylamine hydrochloride solution is titrated in the same manner. The result of the blank experiment is deducted from that for the distillate, and the weight of isopropyl alcohol is given by multiplying this difference by the factor 0.015.

The method of Archibald and Beamer,[69] which is applicable to mixtures of isopropyl and ethyl alcohols, is based on the difference in solubility of sodium hydroxide in the two alcohols. The procedure consists in agitating 10 cc. of the alcoholic mixture with 20 cc. of 30 per cent sodium hydroxide solution, and keeping the mixture at 25° C. during agitation. One cc. of the alcohol layer is then withdrawn and titrated with 0.1*N* sulphuric acid solution. The volume of acid required is then referred directly to a special graph from which the percentage of 91 per cent isopropyl alcohol by volume can be read off. This method can be used when the proportion of isopropyl alcohol does not exceed 50 per cent, most accurate results being obtained with mixtures containing less than 20 per cent isopropyl alcohol. When more than 50 per cent of isopropyl alcohol is present, the original mixture must be diluted with a definite volume of ethyl alcohol and the isopropyl alcohol content of the diluted mixture determined.

When isopropyl alcohol is to be estimated in a mixture of acetone and this alcohol, the acetone content may be determined first by any known method. After oxidation of the isopropyl alcohol the acetone content is determined again, and the difference between the two values thus obtained represents the acetone produced from isopropyl alcohol. According to Cassar [70] the oxidation of isopropyl alcohol to acetone may be carried out quantitatively in the presence of the latter by using chromic acid. By using a definite volume of a chromic acid solution of known concentration and back-titrating the excess acid (with potassium iodide and sodium thiosulphate solution) the amount of isopropyl alcohol in the mixture may be determined in less than one hour. This method is of course applicable only when the alcohol is not mixed with other readily oxidizable materials.

Adams and Nicholls [71] have devised a rapid procedure for the detection and colorimetric determination of acetone, and thus of isopropyl alcohol. This is based on Penzoldt's method,[72] in which indigo is formed as a condensation product when sodium hydroxide is added to a mixture of o-nitrobenzaldehyde and acetone. To 10 cc. of a solution containing not more than 0.02 gram of acetone, add 1 cc. of 1 per cent solution of o-nitrobenzaldehyde in 50 per cent ethyl alcohol, mix, add 0.5 cc. of 30 per cent aqueous caustic soda and allow to stand for 15 minutes, avoiding strong daylight. The color produced is then compared with standards similarly treated. To detect isopropyl alcohol by this method the alcohol is first oxidized with bromine water and the acetone estimated. Five cc. of saturated bromine water is added to 10 cc. of a solution containing not more than 10 per cent by volume of alcohol, and the mixture allowed to stand 3 to 6 hours, or longer, in a cold place. The acetone produced is then determined colorimetrically as just described.

DERIVATIVES OF ISOPROPYL ALCOHOL

The large scale production of isopropyl alcohol has made possible the preparation and study of a large number of derivatives of this alcohol, hitherto unknown or known only in relatively small amounts. Already some of these derivatives are finding important applications in industry while others are being investigated.

Isopropyl Ether. Of the derivatives of isopropyl alcohol, isopropyl ether is becoming important as an industrial solvent. It is a liquid with a sweet and somewhat camphoraceous odor, boiling point of 67.5° C., and specific gravity 0.7247 (20°/20° C.). It is made on a large scale by the dehydration of isopropyl alcohol by means of warm, moderately concentrated sulphuric acid, though other acids may also be used. Apparently the catalytic dehydration of isopropyl alcohol in contact with ordinary dehydrating oxide catalysts, such as alumina, at higher temperatures, leads almost exclusively to the formation of propylene.[73] Even when using sulphuric acid of less than 85 per cent concentration, much propylene is always produced simultaneously with the isopropyl ether. Thus Mann[74] prepared this ether by heating a mixture of isopropyl alcohol and dilute sulphuric acid of 70 to 85 per cent concentration to 100° to 125° C. and condensing the ether from the vapors evolved. The gaseous propylene, simultaneously formed, is absorbed in sulphuric acid and isopropyl alcohol recovered. For example, 75 per cent sulphuric acid is mixed with 1.25 to 1.5 times its volume of 90 per cent isopropyl alcohol and the mixture is distilled through a fractionating column, the temperature of the liquid mixture being maintained at 100° to 125° C., and the temperature at the top of the column at 45° to 65° C. The ether is carried over with the gaseous propylene and is condensed, while the propylene is absorbed in concentrated sulphuric acid at about 10° C., or lower, to yield isopropyl alcohol. The yield of ether is approximately 40 per cent of the theoretical.

In another process for the manufacture of aliphatic ethers, the alcohols are heated to temperatures as high as 300° C. under high pressures in the presence of dehydrating catalysts.[75] Thus on heating isopropyl alcohol in a closed vessel with aluminum sulphate for 4 hours at 210° to 215° C. under a pressure of 53 to 100 atmospheres, a yield of isopropyl ether amounting to 14 per cent of the theoretical was obtained. The process is also applicable to the production of other dialkyl ethers. Purification of isopropyl ether by 65 to 80 per cent sulphuric acid, followed by dilution with water, separation of the insoluble ether and distillation, has been described by Buc.[76]

Isopropyl ether has been suggested as a solvent[77] for animal, vegetable and mineral oils, and for certain waxes and resins. It may be employed also in the extraction of acetic acid, or other aliphatic acids, from aqueous solutions. Mixtures of this ether and ethyl acetate have been proposed for the same purpose.[78] Acetone containing 5 to 20 per cent of isopropyl ether can be used in the preparation of artificial silk of low luster.[79]

[79] Ruth-Aldo Co., Inc., British Patent 385,673, 1931; *Brit. Chem. Abs.* **B**, 1933, 187.

Apparently this ether cannot be successfully substituted for ethyl ether as a solvent in the Grignard reaction.[80] In the presence of isopropyl ether, the reaction between magnesium and the organic halide either does not take place, or else the yield of products is very much less than when ethyl ether is employed.

It has been shown by Clover[81] that this ether, like other simple ethers, slowly takes up oxygen when exposed to the air and sunlight. The products obtained from isopropyl ether are hydrogen peroxide, acetone and isopropyl alcohol; the intermediate substance is probably a peroxide of the type $(C_3H_7)_2O{\cdot}O_2$.

Acetals. Various acetals may be prepared by the action of isopropyl alcohol on the appropriate aldehyde in the presence of a catalyst such as hydrogen chloride, calcium chloride or ferric chloride.[82] Diisopropylacetal, $CH_3CH(OC_3H_7)_2$, is a colorless liquid of boiling point 125.5° to 126.5° C. and d_4^{25} 0.8128.[83]

Isopropyl Chloride. This substance,  $\begin{matrix}CH_3\\ \quad>CHCl\\ CH_3\end{matrix}$, is a pleasant-smelling, non-corrosive liquid of boiling point 36.5° C. and $d_4^{15.6}$ 0.866. It is an excellent solvent for fats and may replace carbon disulphide and petroleum ether to some extent in the fat extraction industry. It may also be used as a refrigerant in certain types of machines. Its application in large scale organic synthesis, though undoubtedly great, is still largely unexplored.[84] This halide may be made by the direct esterification of isopropyl alcohol with hydrochloric acid. Unlike tertiary alcohols, secondary alcohols, of which isopropyl alcohol is typical, do not immediately react with hydrochloric acid alone but readily combine in the presence of an excess of zinc chloride at 26° to 27° C. Primary alcohols do not react with hydrochloric acid under these conditions. This fact may be used to detect the presence of secondary and tertiary alcohols in the presence of a primary alcohol.[85] Norris and Taylor[86] reported that 60 to 82 per cent yields of isopropyl and other alkyl chlorides are obtained by refluxing a mixture of alcohol, concentrated hydrochloric acid, and an excess of zinc chloride.

According to McKee and Burke,[87] alkyl halides may be conveniently produced by passing a mixture of the alcohol and halogen acid in the vapor phase over a catalyst which consists of a solid salt of a bivalent metal, e.g., magnesium chloride, at a temperature of about 300° C.

The halides may be easily freed from polymers by boiling gently with concentrated sulphuric acid under a reflux condenser. The purified chloride is then separated from the mixture either by decantation or by distillation.[88]

The direct esterification of isopropyl alcohol with hydrobromic and hydriodic acids is much more readily effected than with hydrochloric acid.

DIISOPROPYL SULPHATE

Diisopropyl sulphate may be prepared, according to Ormandy and Craven,[88a] by the absorption of propylene in concentrated sulphuric acid at very low temperatures. It may also be obtained in 34 per cent yield by adding isopropyl alcohol slowly to a solution of sulphuryl chloride in carbon tetrachloride at 0° C., followed by washing with ice water and distillation *in vacuo*. The method was employed by Levaillant,[89] who gives the following physical constants for isopropyl sulphate: boiling point 78° to 80° C. at 3.7 mm., d_0^0 1.118, n_D^{17} 1.409. This sulphate may be prepared also by the action of sulphuryl chloride on sodium isopropylate,[90] both dissolved in ether, at temperatures of —10° to —15° C. Isopropyl sulphate should prove useful in introducing the isopropyl group into organic compounds just as methyl sulphate has proved a valuable methylating agent.

The sulphonation of isopropyl alcohol, mixed with high-boiling petroleum fractions, by chlorosulphonic acid at temperatures of about 35° C. yields substances which have been proposed as cleaning, emulsifying or wetting agents.[91]

Isopropyl Acetate. This is undoubtedly the most important of the esters of isopropyl alcohol from an industrial point of view. Ellis and co-workers proposed making this ester by the direct esterification of propylene with acetic acid using sulphuric acid as a catalyst,[92] or by absorbing propylene in sulphuric acid and then adding a salt of acetic acid, such as calcium acetate.[93] Isopropyl acetate is generally made, however, by the esterification of isopropyl alcohol with acetic acid in the presence of a condensing agent, such as sulphuric acid. An example of this esterification process follows:[94] Commercial isopropyl alcohol, containing 10 per cent of water and a little tertiary-butyl alcohol, is distilled with 100 to 200 per cent excess of glacial acetic acid and a catalyst, e.g., 0.2 to 0.3 per cent of concentrated sulphuric acid. The still-head temperature is maintained at 75.5° C. and the isopropyl acetate coming over is condensed and separated from the aqueous layer. Yields of 65 to 80 per cent are obtained before the concentration of acetic acid falls to 65 per cent, at which point the distillation is stopped.

When necessary, isopropyl acetate may be freed from the isopropyl alcohol by water-washing. Mann[95] has devised a process for purifying esters of this type which consists in treating the alcohol-ester mixture with water and a mineral oil distillate [of an initial boiling point of 163° C. (325° F.) or higher]. The alcohol is more soluble in the water than in the oil-ester layer so that separation ensues. The oil-ester layer is separated and distilled to yield the purified ester.

Isopropyl acetate is a colorless liquid of fragrant odor. The boiling point of this substance as formerly given (92° C.) is apparently incorrect, since Grant and Johns[96] report a value of 88.5° to 89.0° C., and Haggerty and Weiler,[97] from an accurate determination of the change of vapor pressure of this substance with temperature, found it to be 88.2° C. The vapor pressure is given by the expression:

$$\mathrm{Log}_{10}\, P = 14.2517 - 2.0972 \log_{10} T - \frac{2170.1}{T}.$$

Its density is 0.877 at 15.6° C.[96]

The technical product has a specific gravity of 0.865 to 0.900, a boiling range of 82° to 95° C. and an acidity of 0.02 per cent acetic acid. It is miscible with benzene to a clear solution in all proportions.[98]

Isopropyl acetate is a good solvent for cellulose nitrate and its evaporation rate, being about one-third that of ethyl acetate, is not rapid enough to cause water blush. Accordingly this ester is useful in pyroxylin lacquers. It is also a good solvent for ester gum, cumarone, elemi, sandarac, mastic, and kauri. It partly dissolves shellac, will not dissolve cellulose acetate or hard copals, and is miscible with hydrocarbons.[98a]

It forms a constant-boiling mixture with isopropyl alcohol (boiling point 80.1° C.) containing 47.5 per cent of ester and 52.5 per cent of alcohol. As previously noted, this mixture has been proposed as a solvent for cellulose nitrate.[99]

Other Isopropyl Esters. The isopropyl esters of organic acids are similar in properties to the corresponding esters of ethyl alcohol. The esters of formic, butyric, valeric, benzoic and salicylic acids have been prepared and may find application in the perfume and essence industry. Isopropyl formate (together with other esters of formic acid) in the vapor state has been found to be toxic to the rice weevil and to have no effect on the germination of wheat. It thus appears to be of value as a fumigant against various stored-products insects. Additions of 60 to 75 per cent by volume of carbon tetrachloride are recommended to free this and other formates of possible fire hazard when thus used.[100] Isopropyl chloroacetate has also been shown to possess a high toxicity and hence to be of value as a fumigant.[101]

Halogenation of Isopropyl Alcohol

The chlorination of isopropyl alcohol yields not only acetone and chlorinated acetones but also chloropropanes and other substances. According to Brochet [102] when isopropyl alcohol is treated with dry chlorine in the cold the product consists mainly of tetrachloroacetone (boiling point 183° C., d^{15}_{4} 1.624, and n^{18}_{D} 1.497). According to Buc [103] the chlorination of isopropyl alcohol to yield chlorinated acetones is best carried out below 70° C., while at higher temperatures the products are chlorinated propanes. Thus it is proposed to manufacture chloropropanes by passing chlorine into boiling isopropyl alcohol. As chlorination proceeds the boiling point of the mixture rises and in the later stages of the chlorination the reaction temperature is maintained at 85° C. The chlorinated product is a heavy liquid which settles out at the termination of the reaction. The products consist [104] mainly of 1,2- and 2,2-dichloropropanes, boiling point 97° to 98° C. and 69.7° C., respectively, and are non-flammable solvents.

Buc [105] has also reported a process for making pentachloroacetone by the chlorination of isopropyl alcohol. Isopropyl alcohol is chlorinated to a mixture of di- and trichloroacetones by treatment with chlorine at 35° to 70° C. (best at

[105] U. S. Patent 1,391,757, Sept. 27, 1921; assigned to Standard Oil Development Co.; *J.S.C.I.*, 1921, **40**, 827B; *Chem. Abs.*, 1922, **16**, 260.

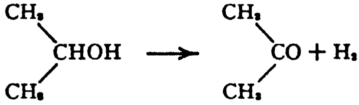
65° C.) under which conditions the formation of chlorinated hydrocarbons is minimized. The chloroacetone may be salted out of solution by inorganic salts. The mixed chloroacetones are further chlorinated in the presence of an excess of water at a temperature of 70° to 100° C. A substantially complete conversion of the lower chloroacetones into pentachloroacetone is effected in 48 to 60 hours.

Dippy, Watson and Yates [106] reported that the principal products of the reaction of bromine and isopropyl alcohol are isopropyl bromide and the unsymmetrical tetrabromoacetone. Along with these products are also obtained some monobromo-, 1,1-dibromo-, and 1,1,1-tribromoacetone.

CONVERSION OF ISOPROPYL ALCOHOL INTO ACETONE

Although acetone is now made very cheaply and economically by certain fermentation processes, isopropyl alcohol from petroleum is available in quantity as a source of this ketone.[107] On the other hand, there appears to be a tendency, especially in Europe where supplies of isopropyl alcohol are not readily available, to utilize acetone as a raw material for the production of isopropyl alcohol.

The conversion of isopropyl alcohol into acetone may be carried out either by catalytic dehydrogenation or by partial oxidation, both reactions resulting in a loss of hydrogen thus:



Where oxidation is employed, the hydrogen is, of course, removed as water. These processes are described more completely in Chapter 18.

SYNTHESES WITH ISOPROPYL ALCOHOL

One of the most important and promising reactions of isopropyl alcohol from an industrial standpoint is its condensation with various aromatic substances to yield isopropylated derivatives. In this reaction, which is brought about under the influence of a condensing agent such as sulphuric acid, the isopropyl alcohol probably functions as a source of nascent propylene, since olefins are known to condense with aromatic substances to yield alkylated products. In some cases, n-propyl alcohol, and even propylene itself, may be substituted for its isomer, another indication that propylene is an intermediate in the process.

This type of reaction may be illustrated by a process developed by the I. G. Farbenindustrie A.-G.[108] Nuclear-substituted arylalkylated or cycloalkylated compounds are obtained by treating either carbocyclic or heterocyclic hydrocarbons with the acid sulphuric esters of alcohols having three or more carbon atoms. For example, benzene is alkylated by mixing it with the acid sulphuric ester of isopropyl alcohol (from chlorosulphonic acid and isopropyl alcohol), adding sulphuric acid, and warming.

This type of synthesis has been extended to the preparation of mixed ethers.[109] To illustrate, isopropyl ter.-butyl ether is made by heating a mixture of isopropyl alcohol and ter.-butyl alcohol, in the presence of sulphuric acid, to temperatures of about 100° C.

Many of the isopropylated derivatives of aromatic hydrocarbons are wetting, emulsifying, and foam-producing materials. It has been proposed to add sulphonic acid salts of isopropylnaphthalene to acid fiber-treating baths such as are used in carbonization of woolen fabrics or in dyeing.[110] Aqueous solutions of sulphonic acids of polynuclear isopropylated aromatic hydrocarbons are said to be of aid in the hydrolysis of fats, oils and waxes.[111] Another application of these emulsifying agents is in the conversion of insoluble substances such as resins or dyes, into emulsions or suspensions. The insoluble substance is first dissolved in a liquid immiscible with water and the solution is emulsified in water with the aid of, e.g., isopropylnaphthalenesulphonic acid. Emulsions of dyes or lakes may be used for dyeing many classes of materials.[112]

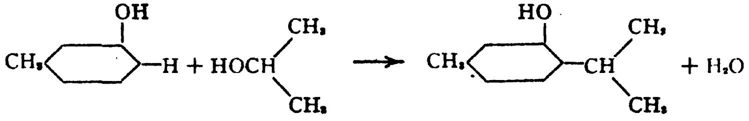
Production of Thymol

Isopropyl alcohol may be used as an isopropylating agent in the production of thymol. The starting materials are m-cresol and isopropyl alcohol (or propylene) and the reaction may be represented as follows:



Thymol

The condensing agent may be phosphoric acid,[113] but sulphuric acid is usually recommended. Thus, m-cresol is sulphonated to a mixture of di- and tri-sulphonic acids by treatment with oleum at 150° C. To this mixture is then added a solution of isopropyl alcohol in concentrated sulphuric acid and the whole is maintained at 90° C. for several hours. The product is then steam-distilled to yield thymol, the sulphonic acid groups being split off during the step.[114] Instead of isopropyl alcohol, n-propyl alcohol may be employed.[115] According to the Rheinische Kampfer Fabrik,[116] thymol may be produced by heating m-cresol with isopropyl (or n-propyl) alcohol in an autoclave at 350° C., in the presence of catalysts effecting the conversion into propylene. Water is distilled off and the heating is repeated after the addition of more alcohol. The yield of thymol is equivalent to 60 to 70 per cent of the unrecovered m-cresol. If propyl chloride is used as a source of propylene, zinc oxide or other acid absorbent is added.

Various syntheses from isopropyl alcohol, including a method for the production of thymol, have been described by Bert.[117]

Thymol is a crystalline solid (melting point, 51.5° C. and boiling point, 232° C.) and an important antiseptic. It is widely used in dentifrice and mouthwash preparations and forms a component of many ointments, soaps, and embrocations used in treating skin diseases.

Chapter 16

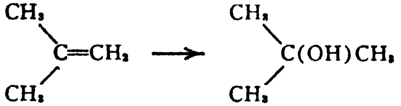
Reaction of Sulphuric Acid with Higher Homologues of Ethylene and Propylene. Production of Higher Secondary and Tertiary Alcohols

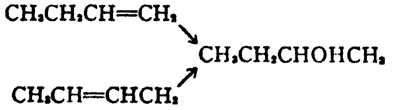
Esterification of the olefins of more than three carbon atoms with sulphuric acid is a more complicated reaction than that of propylene. The extent to which side reactions (polymerization and splitting of the polymers) proceeds depends very largely on the molecular structure of the olefin and on the experimental conditions, especially the acid concentration and temperature. The higher olefins react much more rapidly with sulphuric acid than either ethylene or propylene, so that it is possible to effect reaction by using acid of comparatively low concentrations. Fairly dilute acid is indeed usually essential for good yields of higher alcohols, since more concentrated acid causes considerable polymerization and it is impossible to obtain alcohols from some olefins even by using comparatively dilute acid on this account.

A résumé of the work on the reactions of individual olefins with sulphuric acid is given in this chapter. Industrial processes for the manufacture of the higher secondary and tertiary alcohols will be discussed together rather than as subdivisions under each individual olefin.

THE BUTENES

The tendency of olefins to form alkylsulphuric esters first increases with molecular weight attaining a maximum for the amylenes (pentenes) and hexenes and then declines.[1] The three butenes, particularly isobutene, show a marked affinity for sulphuric acid. Not only are alkylsulphuric acids formed but also (with more concentrated acid) considerable amounts of polymers. However, under certain conditions (namely at fairly low temperatures with sulphuric acid of sufficiently low concentrations) all the butylenes may be converted into the corresponding alkylsulphuric acids and subsequently hydrolyzed to alcohols. In this manner isobutene is convertible into tertiary butyl alcohol and the two other butylenes (butene-1 and -2), into secondary butyl alcohol.





$$CH_3CH_2CH{=}CH_2 \searrow \quad CH_3CH_2CHOHCH_3 \quad \nearrow CH_3CH{=}CHCH_3$$

---

[1] Brooks and Humphrey, *J.A.C.S.*, 1918, 40, 822. See also Brooks, U. S. Patent 1,879,599, Sept. 27, 1932; assigned to Petroleum Chemical Corp.; *Chem. Abs.*, 1933, 27, 312.

Of the three butenes, isobutene is by far the most reactive toward sulphuric acid and other reagents. Butlerow[2] studied the reaction of sulphuric acid of different strengths with isobutene. Trimethyl carbinol was produced with a diluted acid containing 5 parts sulphuric acid and 1 part of water. With stronger acid, a water-insoluble oil was obtained. Investigations of the velocity of absorption of isobutylene in sulphuric acid and the formation of polymerized hydrocarbons were carried out by Berthelot.[3] Faworsky and Debout[4] used the reactivity of isobutene with diluted sulphuric acid as a means for separating this olefin from pseudobutylene (butene-2), the former being soluble in diluted sulphuric acid of approximately 17 per cent strength and the latter insoluble. Data on the proportions of the three butenes absorbed by sulphuric acid (in Hempel pipettes with definite periods of shaking) were given by Michael and Brunel.[5] Their results showed that in each experiment the rate of absorption of the butene was approximately proportional to the quantity undissolved. From the experimental results of Michael and Brunel, Davis[6] calculated a specific absorption coefficient, K, for each butene according to the equation

$$K = \frac{1}{t} \ln \frac{1}{1-x}$$

where t = the number of minutes the pipette was shaken, and x = the fraction of olefin absorbed in time t. Table 85 shows the values obtained.

TABLE 85.—*Absorption Coefficients, K, for the Butenes in Sulphuric Acid.*

Olefin	Conc. of H_2SO_4, Per Cent	Temp. ° C.	K
Isobutene	58.6	21–22	47×10^{-3}
Isobutene	58.6	28–29	105×10^{-3}
Butene-2	58.6	28–29	0.54×10^{-3}
Butene-2	76	29–30	10×10^{-3}
Butene-1	76	29–30	5×10^{-3}

On the basis of these figures Davis calculated that the relative rates of absorption of the three butenes in sulphuric acid are in the ratio of the following figures:

Isobutene	280–390
Butene-2	2
Butene-1	1

Later Davis and Schuler[7] reported some important data on the relative rates of absorption of the gaseous olefins by sulphuric acid at 25° C., in which it was shown that:

(1) Propylene and butene-1 dissolve at about the same rates in sulphuric acid of any concentration.

(2) The ratio of the absorption of butene-2 to butene-1 is remarkably constant, being 1.7 to 2.6 for 70 per cent to 87 per cent acids.

(3) The values for isobutene varied in a puzzling manner, but on the average it dissolved about 10 to 80 times as rapidly as butene-2.

ISOBUTENE

The conditions necessary for the conversion of isobutene into tertiary butyl alcohol with sulphuric acid were first elucidated by Butlerow.[8] Isobutene in the liquid state was allowed to react with 2 volumes of 50 per cent sulphuric acid in a sealed tube at room temperature until solution had taken place. The acid was then diluted, carefully neutralized, and distilled. The tertiary alcohol was salted out of the distillate with potassium carbonate. The polymerizing action of even relatively dilute acid on isobutene was also noticed by Butlerow, who found that when a solution of this olefin in 50 per cent sulphuric acid was warmed to 100° C. the dipolymer (di-isobutene) was produced. On introducing isobutene into a cooled mixture of 5 parts of concentrated sulphuric acid and 1 part of water, Butlerow[9] observed the formation of tri-isobutene. According to Nef[10] butene is quantitatively converted into polymers by concentrated sulphuric acid.

The hydration of isobutene to tertiary butyl alcohol may apparently be effected by comparatively dilute organic acids. Miklaschewsky[11] obtained this alcohol by warming isobutene with a 5 to 10 per cent aqueous solution of oxalic acid at 35° to 40° C.

Michael and Brunel showed that isobutene is rapidly and completely dissolved by sulphuric acid of 63 per cent strength at 17° C., but these workers did not differentiate between the formation of alcohols and alkylsulphuric esters, and reactions of polymerization and rearrangement.

A method for the conversion of isobutyl alcohol into tertiary butyl alcohol through the intermediate formation of isobutene was described by Read and Prisley.[12] Isobutyl alcohol is dehydrated at 500° to 520° C. in the presence of alumina on pumice to yield, mainly, isobutene. The isobutene is then cooled and bubbled through three absorption vessels containing kerosene (cooled to about 0° C.) until the volume of the kerosene had increased by about one-half. An equal volume of cooled 50 per cent sulphuric acid is added to this solution and the mixture shaken vigorously for several hours. It was necessary to keep the reaction mixture cooled to about 0° C., but toward the end of the agitation the temperature was permitted to rise to that of the room. The mixture is allowed to stand to separate the kerosene layer, and the acid layer is neutralized by pouring it, drop by drop, into a well-cooled aqueous solution of sodium hydroxide. The alkaline solution is distilled and the tertiary alcohol salted out of the distillate in the usual way. Under these conditions the other butenes present in the gas are unchanged. It should be noted that great care is required in recovering the tertiary alcohol from the acid solution because of the ease with which this alcohol is dehydrated to isobutene. As dehydration takes place readily in the presence of dilute acids, neutralization of the acid before distilling is essential.

BUTENE-1 AND -2

The conversion of butene-2 into secondary butyl alcohol was investigated by King.[13] The liquefied olefin was agitated under its own pressure in contact with acids of varying strength. At higher acid concentrations polymerization took place, but with 78 per cent acid the formation of polymers was very slight. Acids below this strength yielded normal reactions. In one case an absorption of nearly 21 per cent in excess of the butene theoretically required to give butylsulphuric acid was observed. This suggested that the latter is capable of directly hydrating butene-2. Distillation with water produced a good yield of secondary butyl alcohol. The results of the experiments in relation to acid concentration, absorbed butene in grams per 50 cc. of acid, and time are shown in Table 86.

TABLE 86.—*Absorption of Butene-2 by Sulphuric Acid.*

Acid Conc. (per cent)	Butene-2 in Grams	Time
100	17	——
84	21	5 minutes
78	23	20 minutes
76	22	40 minutes
75.3	22	1 hour
72.5	19	1–6 hours
70	24	5 hours
64.8	10	8 hours
50	22	Little effect after 15 hours

With 100 per cent acid the absorption accompanied by the formation of polymers was complete in a few seconds. With 84 per cent acid, alcohol was the main product, although considerable polymerization occurred. With 78 per cent acid, a trace of an oil with a turpentine-like odor was observed on dilution with water. This was imperceptible with lower concentrations. With higher concentrations a considerable rise in temperature was noted, but with 75 per cent acid the temperature did not reach 40° C. Dilution of the acid solution before distillation with an equal weight of water was adopted as giving the best yields (about 89 per cent) of alcohol. From secondary butyl alcohol, methyl ethyl ketone was obtained by dehydrogenating over reduced copper at approximately 290° C.

The Weizmann and Legg[14] process for the manufacture of secondary butyl alcohol consists in mixing liquid normal butene with cooled 75 per cent acid and subsequently diluting and distilling the acid solution.

A somewhat similar method is described by Newman.[15] The butene (possibly a mixture of isomers made by dehydrating n-butanol at 360° C.) is compressed and treated with 60 per cent sulphuric acid. The reaction is highly exothermic and some dibutyl ether is formed. After the absorption, the acid liquor is diluted, distilled and the secondary alcohol recovered from the distillate. This alcohol can be dehydrogenated catalytically to yield methylethyl ketone. The efficiency of this latter operation was stated to be 90 per cent.

The profound polymerizing effect (accompanied also by rearrangement and splitting of the polymers) of 98 per cent sulphuric acid at 25° C. on the mixture of butenes, resulting from the dehydration of n- and iso-butyl alcohols at 350° to 400° C., was observed by Ormandy and Craven.[16] They were unable to isolate alcohols or alkylsulphuric acids but found the reaction products to consist of a mixture of paraffin and highly unsaturated hydrocarbons.

[16] *J.S.C.I.*, 1928, 47, 317T. Whitmore and Wrenn (*J.A.C.S.*, 1931, 53, 3136) determined the isomers in the "diisobutylene" obtained on treating commercial tertiary butyl alcohol with diluted sulphuric acid (see Chatper 26).

THE PENTENES (AMYLENES)

The five isomeric pentenes have been the subjects of much investigation but it is only in the last few years that their reactions with sulphuric acid have been made clear. Much of the earlier work is contradictory on account of the fact that mixtures of isomers (obtained in various ways) were investigated and because the isolation of pure individual pentenes is often a matter of extreme difficulty. Etard[17] investigated commercial amylene and found it to contain four isomers. Two, ethylmethylethylene and trimethylethylene, are soluble in sulphuric acid diluted with half its volume of water (about 66.6 per cent acid). Two, isopropylethylene and "normal amylene", are insoluble in this acid.

The experiments of the earlier investigators, however, pointed to the conclusion that although amyl alcohols could be produced by the action of sulphuric acid on amylenes, polymerization always played an important part. Thus, Berthelot noted that small quantities of amylene hydrate were formed by the action of sulphuric acid upon "amylene". Erlenmeyer observed only the formation of a dimer, diamylene, under the influence of this reagent. His failure to obtain an alcohol[18] from "amylene" by the sulphuric acid reaction even led him to the conclusion that this hydrocarbon apparently did not belong to the same series as propylene and hexylene, which could be transformed into the alcohols by this method.

Flavitsky[19] conducted a slow stream of carbon dioxide charged with amylene vapor into a mixture of 2 parts of sulphuric acid and 1 part of water. A portion of the amylene was converted into diamylene but the rest dissolved, and, on the addition of water, an alcohol separated from this solution. The alcohol boiled between 100° and 108° C. and was thought to consist in part of dimethylethylcarbinol (tertiary amyl alcohol). Later Osipoff[20] treated commercial amylene with sulphuric acid of various concentrations. With acid of 1.67 sp. gr. (at 20° C.) he obtained an alcohol, believed to be identical with dimethylethylcarbinol. The product was a colorless liquid, smelling like camphor and bitter almond oil, boiling at 96° to 97° C. and solidifying at —30° C. With acid of 1.545 sp. gr. (at 20° C.) the resulting alcohol had a boiling point of 102°-103° C. and did not solidify at —30° C. (probably methylisopropylcarbinol).

The formation of polymers by the action of sulphuric acid of various strengths on "amylene" (usually a mixture of isomers) was noted by a number of observers. Thus, Butlerow[21] found that when amylene, prepared from tertiary amyl alcohol, was mixed with sulphuric acid (2 volumes of concentrated acid to 1 volume of water), diamylene separated. Wischnegradsky[22] stated that amylene, of boiling point 35° C., when shaken with sulphuric acid, sp. gr. 1.64, dissolves after a time and on standing two days gives diamylene. Amylene prepared by the action of zinc chloride on fermentation alcohol was only partially soluble in acid diluted with one-half its volume of water.[23] Wischnegradsky[24] also noted that isopropylethylene did not dissolve at 0° C. in acid diluted with one-half of its volume of water. He claimed[23] to have obtained large amounts of fusel oil by the action of cold concentrated acid on "amylene", the alcohol being isolated by diluting the acid layer with water, thus precipitating an oil consisting, in part, of an amyl alcohol. It must be remembered that isopropylethylene is the most stable of the amylenes, and is therefore an important constituent of "amylene". Under certain conditions, however, it isomerizes to trimethylethylene.[25] Schneider[26] described the preparation of diamylene from amylene (boiling point 35° to 37° C.) by mixing it with twice its volume of sulphuric acid (2 volumes of concentrated acid to 1 volume of water).

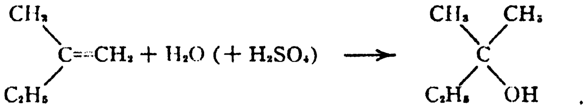
[24] *Ann.*, 1878, 190, 354.

One of the first systematic studies of the relative reactivities of the lower olefins was conducted by Michael and Brunel,[27] who observed that tetramethylethylene reacts readily and completely with 77 per cent acid at ordinary temperatures but not so readily as trimethylethylene. Unsymmetrical methylethylethylene dissolved more readily in 66 per cent acid than did isopropylethylene. One of the amylenes, namely unsymmetrical methylethylethylene, prepared by the dehydration of dimethylethylcarbinol, was found by Brooks and Humphrey[28] to be completely dissolved in 2 volumes of 85 per cent sulphuric acid in a few minutes at 10° C. A 45 per cent yield of the tertiary alcohol was liberated from the solution by diluting with ice water, and no formation of polymers was observed. Apparently the hydration of this methylethylethylene proceeds according to the reaction:



The relative rates of absorption of trimethylethylene and isopropylethylene, compared with those of the lower olefins, in sulphuric acid were examined by Davis and Schuler.[29] They reported that trimethylethylene vapor was absorbed three to four times faster than gaseous isobutene by 80 per cent acid and 1.3 times faster by 70 per cent acid. Isopropylethylene was absorbed slowly by 70 per cent acid at a rate comparable with that of propylene.

A comprehensive work on the action of sulphuric acid on the individual pentenes is that of Norris and Joubert.[30] With the possible exception of pentene-1, all the amylenes were prepared in a pure state and the relative reactivities tested.[31] Equimolecular quantities of olefin and sulphuric acid of various concentrations were introduced into tubes, sealed, and shaken. The progress of the reaction was observed by the changes in the volumes of the contents of the tubes at various time intervals. Amylenes having two radicals linked to an unsaturated carbon atom (e.g., trimethylethylene and unsymmetrical methylethylethylene) reacted much more rapidly with acids of lower concentration than did their isomers. Thus, at room temperature trimethylethylene and unsymmetrical methylethylethylene dissolved in an equimolecular quantity of 60 per cent acid in approximately one-twentieth of the time required to effect solution of either pentene-1 or pentene-2. Norris and Joubert arranged the amylenes in the following order based on the decreasing rate of reaction with sulphuric acid: (1) trimethylethylene, (2) unsymmetrical methylethylethylene, (3) symmetrical methylethylethylene (pentene-2), (4) pentene-1, and (5) isopropylethylene. Whereas the difference in the reactivities of trimethylethylene and unsymmetrical methylethylethylene was slight (trimethylethylene dissolving slightly more rapidly), these hydrocarbons were much more reactive than pentene-2 and pentene-1. Isopropylethylene was affected only by acids of polymerizing strength, and it was impossible to obtain an alcohol from this olefin.[32]

---

[25] Ipatiev, *Ber.*, 1903, **36**, 2004; Senderens, *Compt. rend.*, 1920, **171**, 916.

[26] *Ann.*, 1871, **157**, 207.

[28] *J.A.C.S.*, 1918, **40**, 822.

[29] *J.A.C.S.*, 1930, **52**, 721.

[30] *J.A.C.S.*, 1927, **49**, 873.

[31] The pentene-1, prepared by Norris and Joubert from allyl bromide and ethyl bromide, boiled at 39°-41° C. After their work had been completed Kirrmann (*Bull. soc. chim.*, 1926, **39**, 988), using a similar method of preparation, obtained pentene-1 having a boiling point of 30.5° to 31° C. As pointed out by Norris and Joubert the chief difficulty in this method of preparation is the separation of ethyl bromide, ether and pentene-1, as the boiling points of these substances do not differ greatly. Later Bourguel (*Bull. soc. chim.*, 1927, **41**, 1475) prepared pentene-1 by the catalytic hydrogenation of the corresponding acetylene derivative, and obtained a product boiling at 32.5° C. Following this, Dykstra, Lewis and Boord (*J.A.C.S.*, 1930, **52**, 3396) prepared pentene-1 from its dibromide and found the boiling point to be 29°-31° C. Apparently pure pentene-1 boils about 30°-31° C. and not 39°-41° C. as earlier investigators believed.

To make alcohols from the pentenes (isopropylethylene excepted) it is essential to use acid of the lowest concentration necessary to effect solution at ordinary temperatures. Increasing the concentration of the acid invariably results in the production of polymers. With trimethylethylene slight polymerization was noted using 57 per cent acid, but polymerization was complete in two days in contact with 70 per cent acid. Unsymmetrical methylethylethylene gave similar results. With pentene-1 and pentene-2, much stronger acid (84 to 86 per cent) was needed to give noticeable polymerization. Isopropylethylene was the only pentene which did not dissolve in sulphuric acid, although 75 per cent acid produced complete polymerization in six days. The experiments of Norris and Joubert further showed that relatively small quantities of concentrated acid are capable of effecting almost complete polymerization. When 10 moles of trimethylethylene were shaken with 1 mole of concentrated sulphuric acid, immediate polymerization occurred, the product consisting mainly of the dimer. Using similar proportions of olefin and acid, isopropylethylene yielded with concentrated acid a product boiling above 200° C. (no dimer) and with 75 per cent acid after 7 days, a material consisting almost entirely of the dimer.

These investigators also gave some information regarding the conditions necessary for the production of alcohols from several of the pentenes. Thus, it was found that the addition of ammonium sulphate to a solution of olefins in sulphuric acid (the ammonium sulphate reacting with sulphuric acid to give ammonium acid sulphate) produced interesting results. With hydrocarbons yielding tertiary amyl alcohol, the latter was immediately precipitated in the free state, but from solutions of pentene-1 and pentene-2, the alcohol did not separate until water had been added to permit hydrolysis. On the basis of this observation it was believed that the formation of alcohol was the result of the direct addition of water to an olefin under the catalytic influence of sulphuric acid. In the case of secondary alcohols, subsequent combination of the alcohols (so formed) with sulphuric acid to yield alkylsulphuric acid must be assumed. It was noted that about five equivalents of trimethylethylene could be converted into tertiary amyl alcohol by shaking successive amounts of the olefin with 46 per cent sulphuric acid. The free alcohol was obtained by extraction with ether or by the addition of ammonium sulphate.

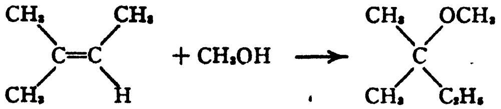
Pentene-1 and pentene-2 can be readily converted into alcohol, according to Norris and Joubert, by shaking the hydrocarbon with an equal volume of 84 per cent sulphuric acid, diluting the solution with 8 volumes of water, and distilling the mixture. The portion of the alcohol dissolved in the aqueous distillate is precipitated by adding salt or sodium hydroxide. The time required for solution of the olefin in the acid can be shortened by using 86 per cent acid, provided the reaction mixture is kept cool.

Direct hydration of trimethylethylene to tertiary amyl alcohol in the presence of a 5 to 10 per cent aqueous solution of oxalic acid at 100° C. for a few days was observed by Miklaschewsky.[33]

---

[32] Michael and Zeidler (*Ann.*, 1911, 385, 252) found, however, that with 10 volumes of either 38 or 47 per cent acid, solution of unsymmetrical methylethylethylene took place in approximately seven-tenths of the time required by trimethylethylene.

The direct combination of methyl alcohol and trimethylethylene,[34] in the presence of sulphuric acid as a condensing agent, at 95° C. results in a 50 per cent yield of a methyl amyl ether, boiling point 86° C. The reaction may probably be represented as follows:



According to Norris and Davis,[35] the butenes and pentenes may be divided on the basis of (a) their reactivity with sulphuric acid, (b) the alcohols produced, and (c) their tendency to form high-boiling oils into the following three main groups:

Group 1. Members of this group dissolve readily in 60 to 70 per cent sulphuric acid, yielding tertiary alcohols, and are easily polymerized by hot dilute acid or by concentrated acid in the cold. They are (1) isobutene, (2) trimethylethylene, and (3) unsymmetrical methylethylethylene.

Group 2. Almost insoluble in sulphuric of any concentration. Yield no secondary alcohol and only a trace of tertiary alcohol and are polymerized more slowly than the members of Group 1. The only member of this group is isopropylethylene.

Group 3. Members of this group dissolve in moderately concentrated acid (75 to 80 per cent) and the products, on immediate hydrolysis, yield secondary alcohols. They are much more resistant to polymerization than the members of Groups 1 and 2. This group includes butene-2, butene-1, pentene-2, and pentene-1.

The above classification corresponds closely with results obtained in the large-scale production of alcohols in which a complex mixture of olefins is split up into these groups by absorption in sulphuric acid of graded concentrations.

The Hexenes

Erlenmeyer and Wanklyn[36] were among the first to investigate the reaction of sulphuric acid with hexene. By varying the concentrations of the acid used, different results were obtained. Thus, 99.3 per cent acid yielded polyhexenes, and the same acid plus one volume of water furnished the β-hexylalcohol. Experiments on the sulphuric acid absorption of butylethylene were carried out by Brochet,[37] who found that this olefin was insoluble in a mixture of three parts of sulphuric acid and one part of water. Le Bel,[38] however, studying the pyrolytic decomposition of the oils derived from bituminous substances (from the mines of Schwabwiller, Pechelbronn and Lobsanne), observed the transformation of hexene into isohexyl alcohol by absorption in sulphuric acid followed by the addition of water and distillation.

Brooks and Humphrey[39] examined the action of sulphuric acid on the straight-chain olefin hydrocarbons of more than five carbon atoms. They concluded that the tendency of aliphatic hydrocarbons to form alkylsulphuric esters and alcohols increases with increasing molecular weight, reaching a maximum with the pentenes and hexenes. Reference has already been made to the observation of Brooks and Humphrey that on pouring a solution (obtained by dissolving simple olefins such as the hexenes in 85 per cent sulphuric acid at temperatures not above 15° C.) into iced water the free alcohol corresponding to a proportion of the olefin dissolved is immediately precipitated, while ordinarily about 30 per cent to 40 per cent of the hydrocarbon remains in the diluted solution in combination as the alkylsulphuric ester. On treating a mixture of hexenes with 100 per cent acid, no alcohols were formed. Larger yields of alcohol were obtained using 85 per cent than 94 per cent acid. It was concluded that the water initially present in the reaction mixture, and not the water in the subsequently diluted solution, enters into the reaction.

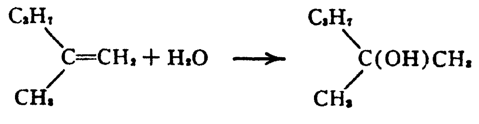
Pursuing these investigations, Brooks and Humphrey studied the action of sulphuric acid on a number of hexenes and mixtures of hexenes. They treated 200 grams of a mixture of hexenes (produced by the action of alkali on mixed monochlorohexanes) with 1.25 moles of sulphuric acid (d 1.84), the temperature being allowed to rise to 40° C., and obtained 117 grams of a mixture of hydrocarbons (unchanged hexenes, dimers, and higher polymers). The acid layer on dilution yielded 58 grams of an oil (probably a mixture of hexyl alcohols), and the aqueous layer was proved to contain hexylsulphuric acids. A summary of the work on hexene-1, 2-methylpentene-1, and tetramethylethylene, is given below.

Fifty-two grams of pure hexene-1 were added to 100 cc. of 85 per cent acid at 15° C. during a period of about 20 minutes. Complete solution to a clear, viscous, amber-colored solution took place. The solution was poured into 4 volumes of water and cracked ice. Separation into two layers occurred, the bulky supernatant layer consisting of hexylsulphuric acid and free alcohol. On adding 6 volumes of cold water to this supernatant liquor the hexylsulphuric acid passed into solution and the free alcohol layer remained. From this layer 28.0 grams of the free alcohol, of d_{20}^{20} 0.823, was recovered. This secondary hexyl alcohol distilled at 134° to 138° C. and on acetylation yielded an acetate boiling at 154° to 158° C. The hexyl alcohol prepared in this way probably has the constitution, $CH_3CH_2CH_2CH_2CHOHCH_3$. No polymers were formed from hexene-1 under these conditions.

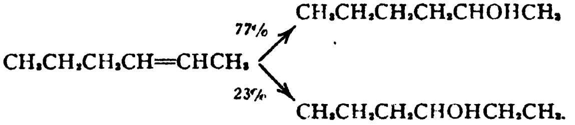
Twelve grams of 2-methylpentene-1 (unsymmetrical n-propylmethylethylene) were treated with 2 volumes of 85 per cent acid at 10° C. The oil lost 55 per cent of its volume by solution. On diluting with iced water, 4.5 grams of a light yellow oil were obtained having a strong camphor-like odor common to all tertiary alcohols. The hydration had evidently resulted in the production of dimethyl-n-propylcarbinol:



From the treatment of 46.5 grams of tetramethylethylene with 150 grams of 85 per cent sulphuric acid at 0° C. for one hour, followed by another hour's standing in which the temperature rose to 15° C., Brooks and Humphrey obtained 37.6 grams of a mixture of hydrocarbons, of which the dimer appeared to be the main constituent. On diluting the acid layer with water, only 1.6 grams of a tertiary alcohol (dimethylisopropylcarbinol) precipitated. The diluted acid liquor, after neutralization with barium carbonate, yielded 20.2 grams of soluble barium salts, accounting for 7.1 grams of the original olefin. Evidently to obtain good yields of the tertiary alcohol, sulphuric acid of considerably lower concentration is necessary.

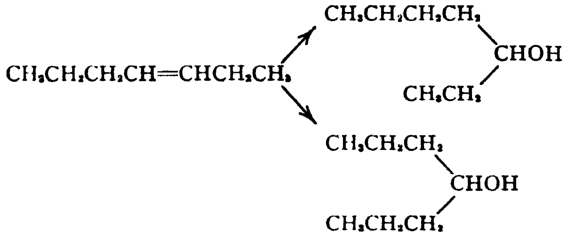
Michael and Brunel observed that tetramethylethylene reacts easily and completely with 77 per cent acid at ordinary temperatures, but not as rapidly as trimethylethylene. The products of the reaction were not, however, examined. The slow hydration of tetramethylethylene, with 5 to 10 per cent aqueous solutions of oxalic acid at 100° C., to dimethylisopropylcarbinol was noted by Miklaschewsky.[40]

According to Michael and Hartman,[41] hexene-2 can react with sulphuric acid in two ways and the hydrolyzed products consist of two isomeric hexyl alcohols in the proportion of 77 per cent of methylbutylcarbinol and 23 per cent of ethylpropylcarbinol, thus



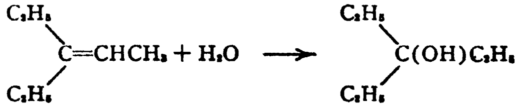
$$CH_3CH_2CH_2CH{=}CHCH_3 \xrightarrow{77\%} CH_3CH_2CH_2CH_2CHOHCH_3$$
$$CH_3CH_2CH_2CH{=}CHCH_3 \xrightarrow{23\%} CH_3CH_2CH_2CHOHCH_2CH_3.$$

The Heptenes. Brooks and Humphrey examined the action of 85 per cent sulphuric acid on 5-methylhexene-1 (iso-α-heptene), heptene-3, and 3-ethylpentene-2. Heptene-3 was remarkable in that it gave no polymers under these conditions. The conversion of heptene-3 into alcohols is apparently more readily effected by the use of benzenesulphonic acid. On adding this olefin to an excess of crystalline benzenesulphonic acid at room temperature, solution took place. After standing for 2 hours, the excess of benzenesulphonic acid was removed from the oily ester by washing with water. Saponification of the benzenesulphonic ester with aqueous sodium hydroxide gives heptyl alcohol, boiling point 134°-136° C. This alcohol probably contains both dipropylcarbinol and ethylbutylcarbinol, produced according to the following scheme:



$$CH_3CH_2CH_2CH{=}CHCH_2CH_3 \longrightarrow \begin{matrix} CH_3CH_2CH_2CH_2 \\ CH_3CH_2 \end{matrix}{>}CHOH$$
$$CH_3CH_2CH_2CH{=}CHCH_2CH_3 \longrightarrow \begin{matrix} CH_3CH_2CH_2 \\ CH_3CH_2CH_2 \end{matrix}{>}CHOH$$

One hundred grams of 3-ethylpentene-2 and 120 grams of sulphuric acid (d 1.84) at 0° C. yielded 21 grams of oil consisting mainly of the dipolymer together with 82 grams of crude alcohol. The latter decomposed during distillation, possessed a strong odor characteristic of a tertiary alcohol, and was probably composed principally of triethylcarbinol.



$$\begin{matrix} C_2H_5 \\ C_2H_5 \end{matrix}{>}C{=}CHCH_3 + H_2O \longrightarrow \begin{matrix} C_2H_5 \\ C_2H_5 \end{matrix}{>}C(OH)C_2H_5$$

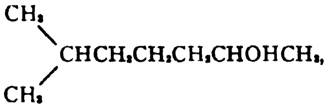
[41] *Ber.*, 1906, 39, 2149.

A further quantity of 6 grams of the tertiary alcohol was recoverable from the diluted acid liquor in the form of its sulphuric ester.

On treating the 5-methylhexene-1 with 85 per cent acid, Brooks and Humphrey obtained a considerable amount of oil consisting mostly of the dipolymer.

HIGHER OLEFINS

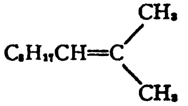
Our knowledge of the action of sulphuric acid on the higher aliphatic olefins is extremely scanty but the work of Brooks and Humphrey indicates that polymerization is always the main reaction. The yields of higher secondary and tertiary alcohols are exceedingly low. Thus, on treating an octene boiling at 122°-124° C. (probably octene-2) with 85 per cent sulphuric acid at 20° C., only a small amount of a secondary octyl alcohol was obtained. Most of the hydrocarbon was converted into polymers. Similarly, 60 grams of α-iso-octene (6-methylheptene-1) and 225 grams of 85 per cent sulphuric acid at 15° C. yielded 48 grams of polymers of which about one-half consisted of the dimer. Only 9 grams of a secondary alcohol, possibly 2-hydroxy-6-methylheptane,



$$\begin{array}{l} CH_3 \\ \quad\diagdown \\ \qquad CHCH_2CH_2CH_2CHOHCH_3, \\ \quad\diagup \\ CH_3 \end{array}$$

were formed.

Brooks and Humphrey also examined the action of 85 per cent acid at 20° C. on 2-methyl-2-undecene,



$$\begin{array}{r} CH_3 \\ \diagup\quad \\ C_8H_{17}CH{=}C\qquad \\ \diagdown\quad \\ CH_3 \end{array}$$

This hydrocarbon was almost entirely converted into a dipolymer with only a trace of higher alcohol. A sample of hexadecene, from spermaceti, was found to be almost unaffected by 85 per cent acid at 20° C., but more concentrated (d 1.84) acid converted it into a mixture of polymers. In general, therefore, it may be concluded that the conversion of the higher olefins into corresponding alcohols by sulphuric acid is a matter of difficulty, probably on account of the instability of these higher alcohols.

INDUSTRIAL METHODS FOR THE PRODUCTION OF HIGHER SECONDARY AND TERTIARY ALCOHOLS

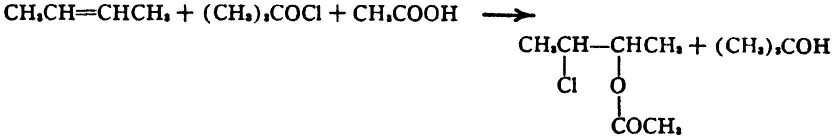
The investigations of Davis and Murray have been referred to in Chapter 14, dealing with the production of isopropyl alcohol. According to the description of the process given in that chapter, three fractions were obtained by the initial fractionation of cracking gas. The treatment of fraction 1, the ethylene-propylene fraction, has been mentioned. Fractions 2 and 3, the butene and pentene (amylene) fractions, will now be discussed.

Fraction 2, containing the isomeric butenes, is first washed with 60 per cent sulphuric acid whereby the highly reactive isobutene is preferentially absorbed. The other two butenes are then absorbed in 80 per cent and at temperatures up to 40° C. (if stronger acid is used the temperature must be maintained below 15° C.). The liquid from the first step, containing tertiary butyl alcohol and its sulphuric ester, is diluted, neutralized with alkali, and distilled to yield the tertiary butyl alcohol. The liquid from the second step is diluted and distilled (without previous neutralization) to give secondary butyl alcohol.

The amylene fraction (fraction 3) consists preponderantly of amylenes with possibly some hexenes and higher olefins, as well as diolefins and less than 5 per cent of paraffins. This liquid may be submitted to a fractional distillation to yield the following fractions: (a) b.p. up to 25° C., mainly isopropylethylene; (b) b.p. 25° to 45° C., consisting of pentene-1, pentene-2, unsymmetrical methylethylethylene, and trimethylethylene; and (c) b.p. above 45° C., containing hexenes and higher olefins. The conversion of isopropylethylene from fraction (a) into an alcohol is not a part of their process. It is stated that by treating fraction (b) with concentrated hydrochloric acid, tertiary amyl chloride is formed together with a mixture of dichloride and unsaturated chlorides (probably derived from admixed diolefins). This mixture may yield, on hydrolysis, tertiary amyl alcohol.[42]

Alternatively the whole of the amylene fraction (3) may be treated with sulphuric acid of 60 per cent strength, which promotes the formation of tertiary alcohols by the hydration of isobutylene, trimethylethylene, and unsymmetrical methylethylethylene, and simultaneously polymerizes the diolefins to heavy oil-like polymers (which may be separated). The unattacked portion of the pentene fraction (a mixture principally of isopropylethylene, pentene-1, and pentene-2) is treated with 77 per cent sulphuric acid, forming the sulphuric esters of secondary amyl alcohols, from which the free alcohols are recovered by dilution and distillation.[43]

Although not strictly within the scope of this chapter it is convenient to mention here a method for the direct esterification of secondary olefins by organic acids.[44] The esterification of secondary olefins of 4 carbon atoms or more with acetic acid or other organic acids proceeds readily at comparatively low temperatures, using equimolecular quantities of reactants, in the presence of catalysts. Sulphuric acid may be used as a catalyst and it is advantageous to add some preformed ester as a solvent. It is interesting to note that butene-2, and other olefins of this type, react with organic acids in the presence of tertiary butyl hypochlorite to yield chloroalkyl esters:



$$CH_3CH{=}CHCH_3 + (CH_3)_3COCl + CH_3COOH \longrightarrow \underset{\displaystyle Cl}{CH_3CH}{-}\underset{\displaystyle \underset{\displaystyle COCH_3}{O}}{CHCH_3} + (CH_3)_3COH$$

Taveau[45] recommended the treatment of olefins, present in cracking gas, and also the volatile liquid products of cracking, with sulphuric acid of various concentrations. The olefin-containing gas is washed with sulphuric acid in a succession of towers so that the olefins are removed successively and a certain degree of separation is effected. Increased pressures may be employed. It is best to allow the acid liquor formed in the absorbing chambers to be diluted immediately as it emerges, either by being poured into water when alcohols are to be produced, or into calcium acetate and water when esters are desired. From cracking gas the various olefins are absorbed in the following order and under the following conditions:

---

[42] The preparation of chlorides and chlorohydrins by treating olefin fractions with hydrogen chloride or hypochlorous acid, respectively, is described by Blanchet, British Patent 251,652, 1926; assigned to Soc. Anon. d'Explosifs et de Prod. Chim.; *Brit. Chem. Abs.* **B**, 1927, 836.

(1) The most reactive olefin, isobutene, is absorbed in 60 to 70 per cent sulphuric acid (best with 65 to 66 per cent) at a temperature not exceeding 30° C.

(2) The isomeric butenes (butene-1 and -2) are absorbed in 80 to 90 per cent acid (best 85 per cent) at a temperature not above 30° C.

(3) Propylene is absorbed in acid of at least 90 per cent concentration, particularly 94 per cent or higher, also at a temperature not above 30° C.

(4) Ethylene is absorbed in highly concentrated acid, such as 98 per cent or higher, at a temperature of 80° to 110° C., and not ordinarily above 120° C.

The corresponding alcohols are made by diluting the acid liquor with 2½ volumes of water at a low temperature and distilling with steam. The resulting distillates from propylene and its homologues separate into two layers, the top layer consisting of water-insoluble alcohols and light polymerization products, and the lower layer of water-soluble alcohols. The top layer must be washed with water to remove any water-soluble alcohols.

Van Peski[46] pointed out that during the absorption of the homologues of ethylene in relatively dilute acid, dilution with ammonium sulphate is equally as efficacious as dilution with water. Since the production of tertiary alcohols always involves the preliminary neutralization of the diluted acid before distillation, this fact is useful in that neutralization may be effected by ammonia (or its salts) with the subsequent formation of ammonium sulphate, part of which is removed and part re-used to dilute more acid. The following example suffices to demonstrate the process: 50.6 grams of 96 per cent sulphuric acid are diluted with 41 grams of an aqueous 40 per cent solution of ammonium sulphate, and a small amount of potassium ferrocyanide added as a catalyst. After dilution, the concentration of the acid is 65 per cent. The acid is brought into contact with 58 grams of technical butene, consisting of 30 per cent of normal butene, 54 per cent of isobutene, and 16 per cent of saturated hydrocarbons. Only the isobutene is absorbed. After absorption the mass is neutralized with 25 per cent aqueous ammonia and distilled, yielding 34.5 grams of pure tertiary butyl alcohol. From the residue, cooled to 0° C., 15 grams of pure ammonium sulphate can be crystallized. The mother liquor (133 grams of 40 per cent ammonium sulphate solution) can be used again for diluting fresh acid. When dilution of the acid is effected with water alone, the other steps being the same, the yield of tertiary alcohol is also 34.5 grams.

Buc[47] obtained reactive acid liquors from mixtures of olefins of different molecular weights by treating them in three successive stages. The concentration of the sulphuric acid in the first stage is below 65 per cent, in the second stage between 78 and 82 per cent, and in the final stage above 90 per cent. The temperature is kept below 120° F. throughout, particularly between 90° and 120° F. in the first and second stages. When gaseous mixtures of olefins are the raw material, a mineral oil, such as gas oil or light lubricating oil, is introduced into each absorption tower. This may be omitted with liquid olefins. This procedure is said not only to minimize polymerization but also to reduce the quantity of acid required. Previously, absorption was always discontinued when about one mole of olefin was absorbed per two moles of acid, but by this method olefins higher in the series than propylene may be absorbed up to about one mole of olefin per mole of acid. After hydrolysis as much as 150 to 170 volumes of higher secondary alcohols per 100 volumes of 80 per cent acid have been obtained and even greater yields of tertiary alcohols.

---

[46] British Patent 341,167, 1931; *Brit. Chem. Abs.* **B**, 1931, 334. French Patent 705,172, 1930; *Chem. Abs.*, 1931, **25**, 5175. U. S. Patent 1,884,405, Oct. 25, 1932; *Chem. [47] British Patent 340,098, 1929; assigned to Standard Oil Development Co.; *Brit. Chem. Abs.* **B**, 1931, 192.

The separation of higher alcohols from the polymerized oils simultaneously formed in the sulphuric acid absorption has offered some difficulty. According to Merley,[48] the alcohols are separated from such oils by using benzenesulphonic acid and a water-soluble alcohol (e.g., isopropyl alcohol) as a selective solvent. This procedure is applicable to the separation of hexyl, or other heavy alcohols, from polymerized oils.

The Bataafsche Petroleum Maatschappij[49] converted cyclic olefins into the corresponding alcohols by treatment with 80 per cent sulphuric acid at low temperatures in the presence of catalysts (ferricyanic acid). The acid liquor (after absorption of the olefin) is poured into iced water, neutralized with alkali and distilled. An example is the conversion of cyclohexene into cyclohexanol.

Brooks[50] recovered alcohols of three to six carbon atoms from the diluted acid liquor polymers by distilling a part of the polymer layer. The alcohols were found in the first runnings. Distillation with steam, according to Brooks, gives a larger yield of alcohols, apparently due to reaction of the steam with certain bodies present in the polymer layer.

SUMMARY

(1) The higher homologues of ethylene show an increasing reactivity toward sulphuric acid with increasing molecular weight, this reactivity apparently being at a maximum with the pentenes and hexenes. Beyond this point olefins of greater molecular weight show a decreasing reactivity toward sulphuric acid.

(2) Direct esterification of the homologues of ethylene is complicated by polymerization and condensation. The tendency toward polymerization is, in general, most pronounced with concentrated sulphuric acid and at higher temperatures. To obtain good yields of alcohols it becomes necessary, therefore, to use acid of as low a concentration as possible (60 per cent or lower in the case of the iso-hydrocarbons) and also to maintain the temperature of the reaction mixture at a low point. Under these conditions there is much evidence to support the conclusion that the dilute acid reacts as a hydrating catalyst, the alkylsulphuric acids being afterwards formed by the esterification of the alcohol. It has also been assumed that esters of hydrated sulphuric acid are first produced and that these are readily hydrolyzed to alcohols. In the case of tertiary alcohols from iso-olefins, direct hydration appears to be the predominating reaction.

(3) The lower olefins vary enormously in their reactivity with sulphuric acid.

[50] U. S. Patent 1,944,400, Jan. 23, 1934; assigned to Standard Alcohol Co.

The iso-olefins are by far the most reactive in the order: isobutene, trimethylethylene, and unsymmetrical methylethylethylene. Next come isopropylethylene, butene-2, butene-1, pentene-2, pentene-1, and finally propylene. The great differences in the rates of absorption may be utilized to effect a partial separation. Thus, the three above-mentioned "tertiary" olefins (i.e., olefins yielding tertiary alcohols on hydration) may be separated more or less completely from secondary olefins by treating mixtures with 60 to 70 per cent acid at 20° C. The more reactive secondary olefins (butene-1, butene-2, pentene-1, pentene-2) are removed from admixed propylene by 80 per cent sulphuric acid at temperatures below 30° C.

(4) The secondary olefins of four and five carbon atoms (excepting isopropylethylene) are easily converted into sulphated materials by approximately 80 per cent acid at 20° C. with relatively little polymerization. The tertiary olefins may be hydrated by 60 per cent acid (or less) also at low temperatures (20° C.). Apparently isopropylethylene is polymerized by sulphuric acid of 80 per cent concentration and over and unaffected by acid of less concentration, so that it is impossible in this manner to prepare the corresponding alcohol in any quantity.

(5) For the treatment of olefins with sulphuric acid, countercurrent scrubbing in towers is usually recommended for gaseous olefins. Liquid olefins are generally agitated with acid in a tank fitted with necessary cooling devices. In treating gaseous olefins, the addition of a neutral liquid diluent (mineral oil) having a solvent action on the olefin is beneficial.

(6) The methods adopted for working up the acid liquor vary in accordance with the character of the alcohol to be recovered. It appears fundamental that tertiary alcohols must be distilled from neutral or slightly alkaline solutions because of the ease with which dehydration proceeds, in the presence of even dilute acids. It is therefore necessary to neutralize the acid liquor with sodium hydroxide, lime, or aqueous ammonia, before distilling off the alcohol. It is usually sufficient to dilute the acid liquor containing secondary alcohols with several times its volume of cold water before distillation.

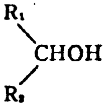
Chapter 17

Properties and Uses of Higher Secondary and Tertiary Alcohols Derived from Olefins

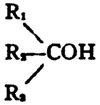
The alcohols obtained by the hydration of the homologues of ethylene are secondary and tertiary compounds in sharp contrast to those produced by fermentation processes which are almost exclusively primary products. These three types of alcohols differ markedly in chemical and physical properties on account of the following characteristic groupings:

RCH_2OH

Primary



Secondary



Tertiary

The divergence in chemical properties associated with their different structures is well exemplified by their behavior on oxidation. When subjected to oxidation the primary alcohols initially yield aldehydes with the same number of carbon atoms and secondary alcohols are readily oxidized to ketones, also with the same number of carbon atoms as the parent alcohol. Tertiary alcohols are characterized, however, by a relatively great resistance to oxidizing agents. When oxidation does occur, a breakdown of the alcohol molecules takes place with the formation of oxidized products of lower molecular weight than the parent alcohol. The marked stability of tertiary alcohols to oxidation is shown by the fact that these alcohols when treated with chromic anhydride form esters of chromic acid, a reaction first investigated by Wienhaus.[1] Another instance of the different chemical natures of these three types of alcohols is their relative ease of dehydration to olefins.[1a] Tertiary alcohols are readily dehydrated to the corresponding (tertiary) olefin by warming with dilute mineral acids and, for this reason, tertiary alcohols cannot be distilled from the diluted acid liquor made by dissolving tertiary olefins in 60 per cent sulphuric acid. Even oxalic acid can dehydrate these alcohols. For example, good yields of isobutylene are obtained by warming tertiary butyl alcohol with oxalic acid. In this reaction stronger acids, such as sulphuric acid, not only dehydrate the tertiary alcohol but tend to polymerize the resulting olefin. Thus, if the alcohol is distilled from sulphuric acid solutions, the relative proportions of the olefin and of its polymers depend upon the quantity and concentration of the acid and upon the conditions of distillation. Primary and secondary alcohols are less readily dehydrated than tertiary alcohols.

Tertiary alcohols are distinguished by the ease with which they combine with halogen acids to form alkyl esters. For instance, when tertiary butyl alcohol is treated with concentrated hydrochloric acid at ordinary temperatures it is converted into the tertiary butyl chloride, which separates immediately. This fact has been made the basis of a test to distinguish these three classes of alcohols. Secondary, but not primary, alcohols are converted into alkyl chlorides by concentrated hydrochloric acid containing zinc chloride.[2] In this, as in other chemical and physical properties, the secondary alcohols occupy a position intermediate between primary and tertiary alcohols. The lability of the hydroxyl group in the tertiary alcohols is inherited by the acid radical which displaces it. Thus secondary butyl chloride is partly hydrolyzed by water and tertiary butyl bromide is converted into the alcohol by cold water. The iodide reacts even more readily and boiling water converts it into isobutylene, simultaneous hydrolysis and dehydration taking place. The remarkable ease with which the tertiary alcohols combine with even weak inorganic acids is exemplified by the ready formation of tertiary alkyl hypochlorites by treatment with aqueous hypochlorous acid.[3]

---

[1] *Ber.*, 1914, 47, 322.

[1a] Whitmore and his collaborators (results reported in *J.A.C.S.*) conducted extensive studies of the dehydration and molecular rearrangement of numerous alcohols.

As distinguished from secondary and primary alcohols, the tertiary alcohols cannot be esterified directly by organic acids, such as acetic acid. Indirect methods must be adopted to obtain these esters, which are very readily hydrolyzed. Tertiary alcohols and acid chlorides, such as acetyl chloride, do not yield organic esters but rather the tertiary alkyl chlorides, in sharp contrast to the behavior of secondary and primary alcohols.

Of the three classes of alcohols, the secondary ones are the most reactive to halogens on account of their reactive hydrogen attached to the alcoholic group. Next in order of reactivity come the primary alcohols, and the tertiary bodies are the most stable toward halogens since they do not contain a hydrogen atom attached to the C—OH group. Davis and Murray[4] reported that solutions of bromine in tertiary butyl alcohol have been used as a laboratory reagent and are quite stable, even in sunlight, but decompose at 80° to 90° C. Tertiary amyl alcohol is also comparatively stable to bromine but the solution is rapidly decolorized at 80° C.

The chemical properties of tertiary alcohols can be understood on the assumption that the bond between the tertiary carbon atom and the hydroxyl group,  $\begin{matrix}\diagdown & & \\ - & C & -(OH) \\ \diagup & & \end{matrix}$, is relatively weak because the valences of the central carbon atom are largely satisfied by the other three radicals attached to this atom. Since this carbon-oxygen linkage is weak the bond O—H is abnormally strong. The stability of this O—H bond is strikingly shown by the behavior of the tertiary alcohols with metals and metallic oxides. Metallic sodium reacts only slowly with tertiary butyl alcohol even at the boiling point of that alcohol. Barium oxide, also, gives no alcoholate so that this tertiary alcohol may be safely dehydrated over these substances. Neither barium oxide nor sodium can be used to dehydrate hexyl and higher tertiary alcohols because of the formation of resins, but tertiary amyl alcohol is stable toward these substances up to about 102° C.

In physical, as well as chemical, characteristics these three types of alcohols show a gradation of properties, the secondary alcohols occupying a position intermediate between the primary and the tertiary. The boiling point and density of tertiary butyl alcohol are approximately the same as that of isopropyl alcohol or of ethyl alcohol. It appears to be a fairly general rule that the physical properties of a tertiary alcohol are similar to those of the homologous secondary alcohol with one less carbon atom in its molecule and of the primary alcohol with two carbon atoms less. The solubilities of the three types of alcohols in water follow the same rule to some extent, but no such similarity exists in the case of refractive indices or freezing points.

Tests for Distinguishing the Three Types of Alcohols

The most convenient method of distinguishing between the three classes of aliphatic alcohols is that given by Kamm,[5] who made use of the difference in the rate with which the alcohols react with hydrobromic acid. The tertiary alcohols react most readily, and the secondary alcohols occupy an intermediate position. Lucas[6] developed a test which consists in treating the alcohol with concentrated hydrochloric acid. Tertiary alcohols immediately react to form insoluble chlorides which rise to the surface in a few minutes. The residual liquid containing, possibly, both secondary and primary alcohols is treated at 26° to 27° C. with about 6 times its volume of a reagent made by dissolving 136 grams of anhydrous zinc chloride in 105 grams of concentrated hydrochloric acid. Under these conditions secondary alcohols yield alkyl chlorides and, on standing, the clear solution becomes cloudy within five minutes. If no change, other than darkening, is observed then secondary alcohols are absent.

Wienhaus[7] described a useful test for some tertiary alcohols. This is based upon their combination with chromic acid. A solution of the substance under examination in carbon tetrachloride or petroleum ether develops a pure red color when shaken with aqueous chromic acid if it contains tertiary alcohols. If the solution rapidly discolors, however, tertiary alcohols are not entirely excluded since these often undergo oxidation. Other methods for the identification of alcohols are given by Shriner and Cox,[7a] Morgan and Pettet,[7b] and Weber and Koch.[7c]

Pharmacology of the Three Classes of Alcohols

Our knowledge of the physiological action of the higher alcohols is rather inadequate but it is generally agreed that toxicity in a homologous series of alcohols, as well as narcotic action, increases with increasing molecular weight.[8] Increase in narcotic action is more rapid than in toxicity. The same increase of toxicity of aliphatic alcohols with increasing molecular weight has been noted in the action of alcohols on spores.[9]

Weese[10] exposed white mice to vapors of aliphatic alcohols at constant temperature with equimolecular amounts volatilized in a constant space. When the air was saturated with alcohol vapors the narcotic and toxic effects increased with the number of carbon atoms in the alcohol molecule. In an atmosphere which was not saturated with alcohol vapors the relationship was somewhat changed, in that n-butyl and isobutyl alcohols were less active as narcotics than propyl alcohol, while secondary and tertiary butyl alcohols were more effective.

The toxicity of tertiary butyl alcohol falls between that of n-propyl and n-amyl alcohols, and of n-butyl alcohol, between ethyl and methyl alcohols.

Measurements of the toxicity of various aliphatic alcohols toward guinea pigs, rabbits, and other animals were made by Rost and Braun.[11] The alcohols were usually administered orally, but also sometimes by injection or inhalation. The effect was qualitatively the same but quantitatively it increased with increasing molecular weight. The study of n-butyl, and secondary butyl, alcohols was complicated by their slight solubility.

SECONDARY BUTYL ALCOHOL (BUTANOL-2)

Secondary butyl alcohol, formed by the hydration of both butene-1 and butene-2, is a colorless liquid possessing a strong, pleasant odor and is without choking action on the bronchial tubes. It has boiling point 99.5° C. (760 mm.), d_4^{25} 0.8022, n_D^{15} 1.3974 and is soluble in 8 volumes of water at 20° C. It forms a constant-boiling mixture with water boiling at 87.5° C. (760 mm.) and having the composition 72.7 per cent of alcohol and 27.3 per cent water. The alcohol also forms a constant-boiling mixture with its acetic ester, containing 13.7 per cent of secondary butyl acetate, and boiling at 99.6° C. The secondary alcohol is, for all practical purposes, non-toxic. It is a solvent for ester gum, shellac, and other gums, castor and linseed oils, and aromatic hydrocarbons, but not for cellulose esters. Although not a satisfactory substitute for normal butyl alcohol in all cases, it is of importance in the lacquer industry mainly in the form of its acetic ester. On treating secondary butyl alcohol with carbon disulphide and sodium hydroxide a xanthate forms which is suggested as a flotation agent, insecticide and vulcanization accelerator.[11a]

The purification of secondary butyl alcohol, made from butylenes in cracking gas, has been the subject of a number of investigations. Lebo[12] proposed to separate the secondary alcohols from admixed isopropyl alcohol, by treatment with benzene, which forms a low-boiling azeotropic mixture with isopropyl alcohol. Merley[13] suggested extracting the diluted acid liquor with water-insoluble, straight-chain hydrocarbons. The latter, together with the dissolved polymers, are removed before distillation of the liquor. Mann[14] dehydrated secondary butyl alcohol by mixing the crude alcohol with a hydrocarbon oil having a high initial boiling point; for example, gas oil of initial boiling point 350° F., mineral seal of initial boiling point of 405° F., or a heavier lubricating oil. On allowing the mixture to separate, the upper layer contains alcohol and oil with a small amount of water and the lower layer consists of water and a small amount of alcohol. By varying the proportion of oil used the extent of dehydration may be varied between wide limits.

Apparently secondary butyl alcohol itself may be used as a dehydrating agent[15] for a number of substances, such as secondary amyl, hexyl and heptyl alcohols. The secondary alcohol forms a constant-boiling mixture with water having the composition by volume of 22 parts of water and 78 parts of alcohol, so that comparatively small amounts of butyl alcohol are required to take up large proportions of water from the higher-boiling liquid. The use of secondary butyl alcohol for dehydrating cellulose nitrate has been described by Wiesel.[16]

ESTERS OF SECONDARY BUTYL ALCOHOL

The most important ester of secondary butyl alcohol is the acetate, which is made on a considerable scale by direct esterification. A process developed by Buc and Clough[17] involves the distillation of a mixture of about 55 per cent of commercial secondary butyl alcohol (as it comes from the finishing run without total dehydration), 45 per cent of strong acetic acid (which need not be glacial but should be of at least 75 per cent concentration) and about 0.1 per cent of sulphuric acid. The upper layer settling from the condensate is refluxed continuously until stratification ceases. The still contents are then distilled, the first fraction boiling within a few degrees of the boiling point of the secondary ester being added to the next batch charge. The second and main fraction, boiling up to within two or three degrees of the boiling point of acetic acid, consists mainly of the desired ester but containing 15 to 30 per cent of acetic acid. The residue in the still, mainly acetic acid, is used in the next operation. The second (or ester) fraction is now subjected to fractional distillation, after addition of sufficient water to form a constant-boiling mixture with the ester. If the water fractionation is carried out carefully, the ester distils over with very little acetic acid. It is then submitted to final purification.

The esterification of secondary butyl and amyl alcohols by organic acids (e.g., acetic acid) can be accomplished in the presence of a solvent in which the solubility of the ester is greater than that of its components or of water.[18] Such a solvent material is a white petroleum fraction of initial boiling point 300° C. and d 1.247.

It is interesting to note in this connection, that when an alcohol, together with the ester of a second alcohol, is passed in the vapor state over an alumina catalyst, partial replacement of the alcohol radical in the ester occurs with the formation of a mixture of esters.[19] Methyl formate and isobutyl alcohol vapors conducted over alumina at 150° C. are converted to the extent of 20 to 30 per cent into isobutyl formate and methyl alcohol.

Secondary butyl acetate having the formula  $\begin{matrix}CH_3CH_2\diagdown \\ CH_3\diagup\end{matrix}CHOOCCH_3$, is a colorless liquid (boiling point 112.2° C.) and is more soluble in water than normal butyl acetate. It possesses a pleasant fruity odor, exerts no choking action on the bronchial tubes, and is considered non-toxic.[20] It is a solvent for cellulose nitrate and for many gums (ester gum, mastic, kauri and benzyl abietate, but it only partly dissolves shellac and dammar). The ester is miscible with castor and linseed oils and hydrocarbons. Cellulose acetate does not dissolve in this ester.[21] Secondary butyl acetate is finding a distinct use in the preparation of lacquers, both as a base solvent and as a thinner.[21a]

[20] The secondary butyl acetate formerly manufactured possessed a disagreeable odor caused by impurities.

A study of the secondary alkyl acetates and their uses in the production of lacquers was made by Park and Hopkins,[22] who emphasized their importance to that industry. The secondary butyl acetate examined by these workers had the following composition and properties: concentration of ester, 85-88 per cent; boiling point 107°-114° C.; $d_{15.5}^{15.5}$ 0.861, n_D^{20} 1.3915. It was an excellent solvent for cellulose nitrate, being intermediate between n-butyl acetate and n-butyl propionate, and somewhat superior to "Pentacetate." [23] The solubility of the ester in water at 25° C. was 1.0 cc. per 100 cc. of water, the corresponding figure for the normal ester being 0.7 cc. Its evaporation rate was intermediate also between that for isopropyl and n-butyl acetate. In blush resistance in lacquers, the secondary butyl ester is similar to the normal butyl compound.

Secondary butyl formate was found by Cotton and Roark [24] to be decidedly toxic, like other alkyl formates, to different kinds of insects and hence to be useful as a fumigant. According to Nelson,[25] secondary butyl formate has a boiling point of 93.6° C. (760 mm.) and its vapor pressure variation with temperature can be represented by the formula:

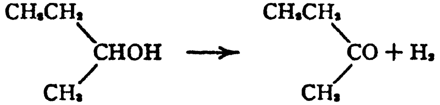
$$\log_{10} P = 8.0306 - \frac{1888.9}{T\ (\text{abs.})}$$

Similarly, secondary butyl chloroacetate, as well as other alkyl chloroacetates, as fumigants were investigated with encouraging results.[26] This ester boils at 167.5° C. (760 mm.) and its vapor pressure has been determined over a wide temperature range.[27]

A possible application of some of the esters of secondary butyl alcohol is in the manufacture of perfumes and flavoring materials.

OXIDATION OF SECONDARY BUTYL ALCOHOL

The oxidation of secondary butyl alcohol offers a convenient method for the preparation of methyl ethyl ketone, an excellent solvent which can replace acetone for many purposes. The reaction is carried out either by catalytic dehydrogenation or by partial oxidation, and may be represented as follows:



$$(CH_3CH_2)(CH_3)CHOH \longrightarrow (CH_3CH_2)(CH_3)CO + H_2$$

Oxidation may be effected by a silver catalyst and dehydrogenation occurs in the presence of reduced copper, other catalysts having been used successfully in both reactions. Thus by the catalytic oxidation of secondary butyl alcohol by air at 335° to 340° C. over a zinc oxide catalyst, Ottensooser [28] obtained a 93 per cent conversion into the corresponding ketone. As an industrial process, it has been proposed to pass the air-alcohol mixture in vapor form over a catalyst heated to at least 500° C., the heat of reaction being sufficient to maintain the desired temperature. Copper, either alone or alloyed with other metals such as zinc, has been suggested as a catalytic material.[29]

TERTIARY BUTYL ALCOHOL (TRIMETHYLCARBINOL)

This alcohol, produced industrially by the hydration of isobutylene, is a solid at ordinary temperatures and possesses the typical camphoraceous odor characteristic of tertiary alcohols. When pure it has melting point 25.45° C.,[30] boiling point (760 mm.) 82.55° C.,[31] and d^{20}_{4} 0.7887. The vapor pressure of a very pure specimen (freezing point, 25.50° C.) of the alcohol was determined by Parks and Barton[32] over a temperature range of 20° to 80° C., with the results given in Table 87.

TABLE 87.—*Vapor Pressure of Tertiary Butyl Alcohol.*

Temperature ° C.	Vapor Pressure mm.	Temperature ° C.	Vapor Pressure mm.
20.00	30.6	60.00	285.2
25.00	42.0	65.00	358.2
30.00	56.9	70.00	447.3
35.00	76.3	75.00	553.2
40.00	102.3	80.00	679.4
45.00	133.8	85.00	826.3
50.00	174.3	90.00	996.2
55.00	224.2		

From these figures the boiling point at 760 mm. is deduced to be 82.86° C. Fundamental thermal data relating to this and other alcohols have been published by Parks, Kelley and Huffman.[33]

Tertiary butyl alcohol is miscible with water in all proportions and forms with it a constant-boiling mixture[34] (boiling point 79.9° C. (760 mm.)) of the composition 88.24 per cent alcohol and 11.76 per cent water, having d^{0}_{4} 0.8304.

Tertiary butyl alcohol is a typical tertiary alcohol, notably in the following particulars:

(1) It is comparatively resistant to oxidation but, under strongly oxidizing conditions. it breaks down to form acetone, carbon dioxide and acetic acid.[35]

(2) It is stable toward halogens.

(3) It is very readily dehydrated by even mild agents such as oxalic acid to yield isobutylene.

(4) It yields halides with remarkable ease on treatment with halogen acids even in the cold. On the other hand, it cannot be directly esterified by organic acids, and organic acid chlorides react with it to form tertiary butyl chloride and the organic acid.

(5) The organic esters of this alcohol are readily hydrolyzed by water even in the cold. Also, the tertiary halides are hydrolyzed readily. If the mixture is warmed the tertiary alcohol so formed undergoes dehydration in the presence of the halogen acid. In this way isobutylene can be prepared from tertiary butyl iodide.[36]

Large quantities of the tertiary alcohol can and have been produced from cracking gas. The great difficulty is to find an outlet for comparatively large amounts of the material. As far as known, tertiary butyl alcohol, as such, has found no extensive applications in the chemical industry, although it can be used for purifying certain substances (for example, the hydroxy acids) by recrystallization from hot solutions. For this purpose a solvent is needed in which the solubility, though low at ordinary temperatures, increases rapidly with rising temperature. A comparison of the effect of temperature on the solubilities of citric acid in water, ethyl alcohol and tertiary butyl alcohol, respectively, indicates that the latter is by far the superior solvent for recrystallizing this acid.[37]

Souther and Gruse[38] investigated the use of higher secondary and tertiary alcohols (having 3 to 6 carbon atoms), and also of the higher primary alcohols, for the purification of slack wax. They found that such alcohols, either individually or mixed with each other, had a preferential solvent action for the oil admixed with the crude wax. Thus, the commonly employed and time-consuming sweating process might be avoided. The slack wax is comminuted with the alcohol for about five minutes, generally at 80° F. to raise the melting point of the final product, and then pressed in a filter press or run through a centrifuge. The resulting wax cake is again mixed with the alcohol or alcohol mixture (n-butyl alcohol having proved especially efficient for this purpose) and centrifuged. If necessary, the last remaining traces of oil can be removed by further treatment with the solvent. Bradley[38a] suggested as a paint-removing composition a mixture containing a wax and tertiary butyl alcohol. The use of tertiary aliphatic alcohols in fuels for internal-combustion engines has been proposed by Van Schaack.[38b]

From the viewpoint of chemical synthesis, tertiary butyl alcohol offers many interesting possibilities. It may be used for introducing the tertiary butyl group, $(CH_3)_3C-$, into organic compounds, especially into aromatic compounds. Nitrated aromatic hydrocarbons and ketones containing this tertiary alkyl group frequently possess a strong musk-like odor and are valuable in the perfume industry.

Tertiary butyl alcohol is a safe material to handle but possesses a slight narcotic action when taken internally, being excreted in the urine in combination with glycuronic acid.[39]

DERIVATIVES OF TERTIARY BUTYL ALCOHOL

Tertiary Butyl Halides. All the halides of tertiary butyl alcohol are readily prepared by mixing the halogen acid (in the form of a concentrated aqueous solution) with the alcohol in the cold, the ester separating as a top layer in a few minutes. The tertiary halides are also made by the direct combination of isobutylene with the anhydrous halogen acid.[40] Tertiary butyl chloride is a colorless liquid boiling at 51.5° C., and the boiling points of the bromide and iodide are 72° C. and 103° C., respectively. From an industrial point of view the chloride only need be considered. The important application of this material will probably be for introducing the tertiary butyl group into organic compounds, especially aromatic hydrocarbons, by the Friedel-Crafts reaction.

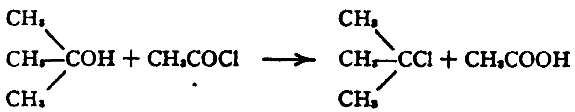
Tertiary Butyl Hypochlorite. In comparison with primary and secondary alkyl hypochlorites the hypochlorite esters of tertiary alcohols are relatively stable. These substances are yellow, mobile liquids of strong, irritating odor and are prepared by passing chlorine into an ice-cold solution of aqueous sodium hydroxide in the alcohol (the solution should be homogeneous) until absorption ceases. The hypochlorite ester separates.[41]

Tertiary butyl hypochlorite, boiling point 79.6° C., d^{18}_{4} 0.9583, may be distilled without change and, unless exposed to sunlight, kept for months at ordinary temperatures with scarcely any decomposition. When exposed to bright sunlight it decomposes to methyl chloride and acetone. Like all tertiary esters, it can be readily hydrolyzed in dilute alkaline solution.

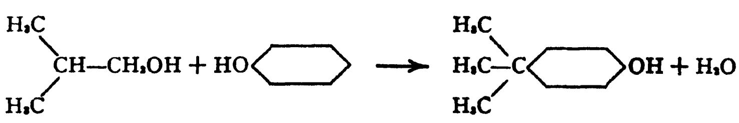
Tertiary Butyl Esters. Esters of tertiary butyl alcohol (and of other tertiary alcohols) appear to be of little promise industrially. They are not readily prepared by the ordinary esterification methods since organic acids dehydrate the alcohols to olefins, and organic chlorides react to form the tertiary alkyl chloride, thus:



$$\begin{matrix}\mathrm{CH_3}\\ \mathrm{CH_3{-}COH}\\ \mathrm{CH_3}\end{matrix} + \mathrm{CH_3COCl} \longrightarrow \begin{matrix}\mathrm{CH_3}\\ \mathrm{CH_3{-}CCl}\\ \mathrm{CH_3}\end{matrix} + \mathrm{CH_3COOH}$$

Tertiary butyl acetate, obtained by the direct combination of ketene[42] with the tertiary alcohol, is a liquid (boiling point 96° C.), possessing a somewhat fruity odor, but readily hydrolyzed by water even in the cold.[43]

Other Important Derivatives of Tertiary Butyl Alcohol. Two products which are finding satisfactory application in the commercial production of phenol-aldehyde oil-soluble resins[43a] are para-tertiary-butyl- and amyl-phenol.[43b] The production of these alkylated phenols by addition of olefins to phenol is described in Chapter 24. Nevertheless, they can be made from tertiary alcohols. The alkylation was effected by Liebmann[43c] by heating phenol with an alcohol in the presence of a large excess of a dehydrating agent such as zinc chloride at 180° C. Thus, by heating isobutyl alcohol and phenol, in the presence of zinc chloride, the following reaction occurs:



Other dehydrating agents, for example, acid sulphates,[43d] sulphuric acid,[43e] and perchloric acid,[43f] have also been suggested.

Phenols can be alkylated by using an alkyl halide in the presence of a metallic halide such as aluminum chloride, ferric chloride, or zinc chloride. In the preparation of para-tertiary-butylphenol, for example, tertiary butyl chloride and phenol are reacted in the presence of a small amount of ferric chloride.[43g] This reaction, which can be represented by the equation

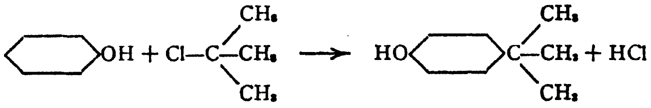
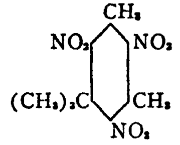
[43f] Hinsberg, German Patent 538,376, 1930; *Chem. Abs.*, 1932, 26, 1617.



has also been effected in the presence of alcoholic potassium hydroxide solution.[43h] Linner[43i] has proposed to conduct the reaction in this manner: Isobutylene is bubbled through a solution of phenol in carbon tetrachloride containing aluminum chloride in suspension and a small quantity of tertiary-butyl chloride. The reaction is instituted by the alkyl chloride and the hydrogen chloride liberated combines with the isobutylene to form additional alkyl chloride to continue the reaction.

Para-tertiary-butyl-phenol melts at 97.5° to 98° C. and boils at 236° to 238° C.; para-tertiary-amylphenol melts at 93° to 94° C. and boils at 265° to 267° C.

The discovery of synthetic materials possessing the odor of musk (and hence termed "artificial musk") was made by Baur,[44] who developed methods for the large-scale production of these synthetic perfumes. Many of them are nitrated aromatic hydrocarbons containing a tertiary alkyl substituent (usually tertiary butyl) such as trinitro-tertiary-butyltoluene, trinitro-tertiary-butylethylbenzene, and trinitro-tertiary-butyl-m-xylene, the last named substance possessing the configuration



,

Not only hydrocarbons but nitrated phenols, aromatic ethers and ketones having a tertiary alkyl substituent were found to possess the characteristic musk-like odor. Among these may be mentioned dinitro-tertiary-butylacetophenone, trinitro-tertiary-butyl-m-cresol, and dinitro-tertiary-butylxylyl methyl ketone.[44a] The tertiary butyl group was introduced into these aromatic compounds by the Friedel-Crafts reaction, using tertiary butyl chloride. The products were then nitrated to yield the synthetic musks.

Some of the derivatives of the tertiary alkylated aromatic hydrocarbons, especially tertiary-butylbenzenesulphonic and tertiary-butylnaphthalenesulphonic acids, have been suggested as wetting, emulsifying, and foam-producing agents. 4-Tertiary-butyl-β-naphthol,

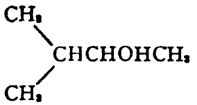
prepared by the action of tertiary butyl chloride on β-naphthol in the presence of aluminum chloride, has been proposed as a plasticizer for cellulose derivatives and as a dye component.[45]

HIGHER SECONDARY ALCOHOLS FROM PETROLEUM

The important higher secondary alcohols which may be manufactured from the volatile liquid olefins are secondary amyl and hexyl alcohols. Secondary heptyl and higher alcohols can be made if there is sufficient demand for them. Heretofore these alcohols have been exceedingly rare and difficult to prepare in any but small quantities. The higher secondary alcohols produced from the olefins of cracking gas and cracked gasoline consist largely of β alcohols, i.e., normal chain alcohols with a hydroxyl group attached to the second carbon atom. According to Johns,[46] laboratory researches (unpublished) indicate that all the secondary alcohols obtained are of this type. It is possible, however, that although the β alcohols may predominate, there may also be a smaller amount of secondary alcohols in which the hydroxyl group is attached to the third carbon atom of the chain. There is an increasing number of isomers even of the β alcohols as the number of carbon atoms in the molecule increases because branched chains may exist. For example, there are two β pentanols which have the following formulas:

$CH_3CH_2CH_2CHOHCH_3$
Methyl-n-propylcarbinol



$$\begin{matrix} CH_3 \\ \quad\searrow \\ \quad CHCHOHCH_3 \\ \quad\nearrow \\ CH_3 \end{matrix}$$

Methylisopropylcarbinol

The secondary alcohols shown in Table 88 are likely to occur in the products obtained by absorbing the higher olefins (from cracking gas or gasoline) in sulphuric acid and hydrolyzing.[47]

Secondary amyl alcohol (*pentanol-2*) has a hydrocarbon-like odor with a slight choking action in the bronchial tubes. It is less soluble in water than the lower secondary alcohols, dissolving in 6 volumes of water at ordinary temperatures. The product made from cracking gas probably contains some of the branched-chain isomer, methylisopropylcarbinol. It may find application in the lacquer industry in the form of its acetate, boiling point 135°-138° C., a mobile liquid with a peppery odor similar to that of turpentine. Park and Hopkins[48] examined a sample of secondary amyl acetate (containing 85 per cent of ester and 15 per cent of alcohol, and having a boiling range of 128° to 134° C., $d^{15.5}_{15.5}$ 0.863, n^{20}_{D} 1.4021). It was concluded that this and other secondary esters could safely be used either in the base lacquer or thinner. These secondary esters are made in the usual way by direct esterification in the presence of a mineral oil fraction of initial boiling point 300° C.[49]

[a] Sherrill, *J.A.C.S.*, 1930, **52**, 1982.

Methylisopropylcarbinol is remarkable in that, on treatment with hydrogen halides, it is converted into the derivatives of methyldiethylcarbinol, a reaction explainable on the assumption that the intermediate formation of trimethylethylene first takes place.

Secondary hexyl acetate is likely to be of value in the lacquer industry.[50] A sample examined by Park and Hopkins had the following properties, 85 to 88 per cent ester, boiling range 146° to 156° C., $d_{15.5}^{15.5}$ 0.863, n_D^{20} 1.4081. It is a solvent for rosin, ester gum, dammar, kauri, cumar, pontianac, manila, elemi, asphalt, tars, and pitches, but not for shellac. Its solubility in water at 25° C. is less than 0.1 cc. per 100 cc. of water.

Secondary heptyl alcohol (*heptanol-2*) may be prepared synthetically by roundabout methods[51] but, if available in sufficient quantities, may find application in the lacquer industry (in the form of its esters[51a]) and for chemical synthesis.

All the secondary alcohols, amyl, hexyl, and heptyl included, may be converted into ketones, particularly by catalytic oxidation. For instance, Ottensooser[52] obtained an optimum yield of 79 per cent of the ketone from secondary octyl alcohol by oxidation with air in the vapor phase at 330° to 340° C. in the presence of a zinc oxide catalyst. In this way it should be possible to make large quantities of the higher ketones (which are excellent solvents for industrial purposes, particularly in cellulose acetate and nitrate lacquers) from the above secondary alcohols. Pentanol-2 would yield methyl propyl ketone and 3-methylbutanol-2, methyl isopropyl ketone. In general, methyl alkyl ketones could be produced from the higher β alcohols.

HIGHER TERTIARY ALCOHOLS FROM PETROLEUM

Formerly the higher tertiary alcohols were more or less chemical curiosities which had been produced only in relatively small quantities or not at all. The possibility of obtaining large amounts of these alcohols from the olefins of cracking gas and cracked gasoline has opened up a wide field for investigation, more especially as regards their application in industry. As far as is known, no outlet has been discovered which is capable of absorbing the large quantities of these materials which might be available. The unique chemical and physical properties of these alcohols, however, appear to render certain their ultimate large-scale utilization in industry either as special solvents and crystallizing media, in chemical syntheses, or for other purposes.

[51] See Sherrill, *J.A.C.S.*, 1930, **52**, 1982. Whitmore and Otterbacher, "Organic Syntheses," John Wiley & Sons, Inc., New York, 1930, 10, 60.

[51a] Van Schaack (U. S. Patent 1,815,878, July 21, 1931; assigned to Van Schaack Bros. Chem. Works, Inc.; *Brit. Chem. Abs.* **B**, 1933, 218) suggested as softeners for cellulose nitrate, the esters of higher secondary alcohols and dibasic acids such as 2-n-octyl succinate or phthalate.

[52] *Bull. soc. chim.*, 1927, (4) 41, 324; *Chem. Abs.*, 1927, **21**, 2089.

The general characteristics of the tertiary alcohols as a class have already been noted in discussing tertiary butyl alcohol, namely their unique physical properties including high melting point and low boiling point, the ease of replacement of the hydroxyl group by halogen acids (and even hypochlorous acid) to form esters, their ease of dehydration in the presence of even weak organic acids, their resistance to oxidation and stability to halogens, the impossibility of direct esterification by organic acids or acid chlorides and the extraordinary ease of hydrolysis of their esters.

Tertiary amyl alcohol (*dimethylethylcarbinol*)  is a liquid at ordinary temperatures, boiling point 101.8° C., melting point —12° C., d^{20}_{4} 0.8093, n^{20}_{D} 1.4052,[53] and possessing a camphoraceous odor. It is soluble in 8 volumes of water at ordinary temperatures. This alcohol is formed by the hydration of both trimethylethylene and unsymmetrical methylethylethylene. It is readily dehydrated, especially in acid solutions, to yield trimethylethylene. It is comparatively stable to bromine at room temperature but the solution rapidly decolorizes at 80° C. Tertiary amyl alcohol is said to be "a safe, rapidly acting, and occasionally useful but not analgesic hypnotic." [54]

Tertiary amyl chloride, which is prepared by the action of concentrated hydrochloric acid on the alcohol, is a liquid boiling at 86° C., which should be useful for introducing the tertiary amyl group into organic compounds. *Tertiary amyl hypochlorite,* made by passing chlorine into an alkaline solution of the alcohol at ordinary temperatures, is a mobile liquid of d^{25}_{4} 0.8547, boiling with decomposition at 76° C.[55]

The properties of the tertiary hexyl alcohols, of which three isomers exist, are very inadequately known. Davis and Murray [56] described two of these alcohols, namely a straight-chain tertiary hexyl alcohol (probably dimethyl-n-propylcarbinol), boiling point 123° C., d^{20}_{4} 0.824, and a branched-chain tertiary hexanol (probably dimethylisopropylcarbinol) of boiling point 117.6° C., and d^{20}_{4} 0.839.

Chapter 18

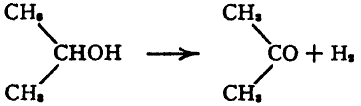
Production, Properties, and Uses of Ketones Derived from Secondary Alcohols and from Hydrocarbons

Ketones are derived from secondary alcohols made by the hydration of the lower olefins of cracking gas and represent an important use for these alcohols. As a class, ketones are among the most valuable solvents of commerce and find application in a number of industries. Acetone, particularly, is one of the most widely used of low-boiling solvents. In addition to being solvents for a large number of organic substances, the ketones also undergo condensation reactions and are thus of significance in organic chemical synthesis.

Although acetone and the higher ketones are still mainly produced from raw materials other than petroleum (for example by fermentation of grain or by wood distillation), the petroleum hydrocarbons offer great possibilities as suitable raw materials for the manufacture of these solvents. The oxidation or direct dehydrogenation of secondary alcohols, made from the lower olefinic hydrocarbons of cracking gas and cracked gasoline, readily yields ketones.[1] It has also been demonstrated that ketones may be synthesized directly from the lower paraffins by the Friedel-Crafts reaction.

PRODUCTION OF ACETONE

Formerly, acetone was principally produced by the destructive distillation of wood, but the greater part of the acetone now available, together with normal butanol, is made by the fermentation of carbohydrate material by the Fernbach-Strange-Weizmann process.[2] Although this method is economical, isopropyl alcohol (derived from the propylene of cracking gas) has been the subject of many investigations directed to its conversion to acetone.[3] The usual methods for the production of acetone in this manner involve either catalytic oxidation of isopropyl alcohol with air or its dehydrogenation by passage (without air) over a heated catalyst. Both these procedures result in the removal of hydrogen:



When oxidation is employed, the hydrogen is, of course, removed in the form of water. Sabatier and Senderens[4] have shown that metallic copper is an excellent dehydrogenating catalyst for primary and secondary alcohols. In the presence of this catalyst, isopropyl alcohol is slowly dehydrogenated to acetone at 150° C., and rapidly and smoothly at all temperatures between 250° and 430° C. without the formation of large amounts of propylene. With many contact substances, dehydration, leading to the formation of propylene, occurs. Many processes have been developed to better the performance of the copper catalyst of Sabatier and Senderens. Metallic sulphides have been recommended,[5] and the phosphides, selenides, tellurides, antimonides, arsenides, and the bismuthates of zinc, cadmium, nickel, cobalt, iron, aluminum, calcium, and magnesium have been suggested[6] as catalysts for the dehydrogenation of alcohols to ketones and aldehydes. Dehydrogenation of isopropyl alcohol to acetone and hydrogen by contact with lead at 625° C. is the basis of another process.[7] Molten lead can be replaced by molten alloys or salts, e.g., an equimolecular mixture of barium and calcium chlorides, or equal parts of potassium and sodium chlorides. Chaffette[7a] suggested halides, oxides, carbonates, phosphates, acetates, stannates, arsenates, antimonates, molybdates, vanadates, and borates of the metals of the second, seventh and eighth groups as catalysts for the production of acetone from alcohols and steam.

[3] Ellis and Wells, *loc. cit.* Baldwin (*J.S.C.I.*, 1930, **49**, 53T, *Ind. Eng. Chem., News Ed.*, 1930, **8** (2), 12.) reported considerable quantities of acetone were being made in the United States from propylene of petroleum origin.

[4] *Ann. chim. phys.*, 1905, (8) **4**, 463, 467.

The dehydrogenation of primary, secondary and tertiary alcohols by catalytic oxidation has been the subject of a number of important researches.

Ipatiev[8] investigated the catalytic oxidation of isopropyl alcohol to acetone at 200° to 230° C. and of secondary butyl alcohol at higher temperatures, using nickel. Trillat[9] investigated the catalytic transformation of isopropyl, isobutyl, isoamyl, and iso-octyl alcohol into the corresponding ketones, using a platinum wire gauze. He also extended his experiments to include tertiary butyl and amyl alcohols which yielded acetone and some formaldehyde. Sabatier and Senderens[10] also studied the catalytic oxidation of secondary and tertiary alcohols by different metals. Isopropyl, isobutyl, and iso-octyl alcohols gave the corresponding ketones in good yields, when copper, nickel, cobalt and platinum were used as catalysts. Gibbs[11] described the production of acetone by catalytic oxidation of isopropyl alcohol, made from the waste gases of the Burton cracking process. Lang[12] developed a method for producing ketones (or aldehydes) in which manganic salts at high temperatures were the catalysts, and Williams and White[13] suggested passing alcohol vapors over brass heated to 500° to 800° C.

Still another procedure consists in conducting isopropyl alcohol vapors and air (the quantity of air being such that the proportion of oxygen in the mixture is just equal to, or slightly less than, that actually required) over metallic catalysts, e.g., copper or copper alloys, at 475° to 800° C. The yield of acetone may be as high as 75 per cent of the theoretical.[14]

Moureu and Mignonac[15] investigated the catalytic oxidation of various alcohols in the vapor state in the presence of finely divided silver (deposited on asbestos by precipitation from silver nitrate solution with formaldehyde) at 230° to 300° C. Intense local heating made it preferable to conduct the operation in two stages, i.e., first to pass the alcohol vapor mixed with 40 to 50 per cent of the requisite amount of air over the catalyst, and then to mix the issuing vapors with a further 50 per cent of air and pass the new mixture over a second catalyst. Excellent results were reported with isopropyl alcohol. This method was subsequently modified[16] in that the mixture of alcohol vapor and air was passed at a reduced pressure (20 to 40 mm.) over a catalyst of finely divided silver at 230° to 300° C. Later, Ottensooser[17] by the vapor-phase oxidation of isopropyl alcohol with air (in the presence of a zinc oxide catalyst prepared from ammonium zincate[18]) obtained an 84.5 per cent conversion of this alcohol into acetone, the optimum temperature being 315° to 325° C. Acetone can be produced by subjecting ethyl alcohol vapor diluted with an inert gas to the action of catalysts at 250° to 650° C.[19]

[15] *Compt. rend.*, 1920, **170**, 258.

The effect of the physical and chemical nature of the catalyst material on the course of the oxidation of various alcohols in the vapor phase was investigated by Simington and Adkins.[20] The catalysts included copper, silver, platinum, nickel, alloys of copper with silver, zinc, bismuth, cadmium and palladium. Gauze, pellets, strip and wire catalysts were equally efficacious. The maximum yield of acetone from isopropyl alcohol, corresponding to a 76.1 per cent conversion, was obtained when using a catalyst of silver pellets.

Other catalysts that have been proposed include the following: a metal vanadate (excluding a simple alkali vanadate),[21] a gauze of zinc-copper alloy,[22] and metallic copper, iron, nickel, silver, platinum or the oxides of tin, chromium, cobalt or vanadium.[23] In general the mixture of air and alcohol in the proportions required (or with slightly less air than is actually necessary) is passed over the catalyst heated initially to about 500° C. The heat of reaction is sufficient to maintain the catalyst at the required temperature. Wells[24] has described certain catalysts, such as manganese dioxide or barium peroxide, to be used at somewhat lower temperatures, i.e., 100° to 250° C.

The catalytic oxidation of isopropyl alcohol to acetone is said to take place readily at 400° C. in the presence of copper, manganese dioxide, barium peroxide, a platinum metal, zinc oxide, cadmium oxide, uranium oxide, blue tungsten oxide, vanadium pentoxide, magnesia, beryllia, or zirconia to which has been added about 1 per cent of thorium oxide, cerium oxide, or other oxides.[25]

Other methods for the manufacture of acetone utilize acetic acid, ethyl alcohol, or acetylene as raw materials. The older method of converting acetic acid into acetone, so largely employed in the wood-distillation industry, consisted in the dry distillation of the calcium salt of that acid. According to Ardagh, Barbour, McClellan and McBride,[26] the optimum distillation temperature is 430°

[26] *Ind. Eng. Chem.*, 1924, **16**, 1133.

to 440° C. This procedure, however, now has to compete with the direct catalytic production from acetic acid which takes place according to the reaction,

$$2CH_3COOH \longrightarrow CH_3COCH_3 + CO_2 + H_2O$$

The reaction is complicated by the simultaneous occurrence of the decomposition of acetic acid to methane,

$$CH_3COOH \longrightarrow CO_2 + CH_4$$

a breakdown which may be reduced by the choice of proper catalysts and operating conditions.[27] A large number of catalysts for the direct synthesis of acetone from acetic acid in the vapor phase has been proposed, among which may be mentioned the following: thorium and uranium oxides,[28] copper at 390° to 410° C.,[29] zinc oxide at 400° C. and zinc turnings at 250° to 280° C.,[30] manganese salts at 450° C.,[31] manganese dioxide at 350° to 450° C.,[32] oxides, hydroxides or acetates of calcium and barium precipitated on aluminum and used at 300° to 400° C.[33] During the World War a commercial process was developed by the Canadian Electro-Products Co. which consisted in passing acetic acid vapor over cast iron balls coated with lime or baryta or a mixture of these with bases such as magnesia. The operating temperature was 485° C. and the yield of acetone was said to be 95 per cent of the theoretical, based on the acid consumed.[34]

Another method of producing acetone depends upon the catalytic treatment of ethanol with steam at high temperatures.[35] The reaction (which yields very pure acetone together with hydrogen and carbon dioxide) may be represented:

$$2CH_3CH_2OH + H_2O \longrightarrow CH_3COCH_3 + 4H_2 + CO_2$$

Probably it involves several intermediate steps, including the possible formation of acetic acid.[35a]

Donath[36] investigated the oxidation of ethyl alcohol to acetone at high temperatures in the presence of the higher oxides of manganese, and Roka[37] examined the production of acetone by heating a mixture of ethyl alcohol and water vapors at 250° to 650° C. in the presence of oxygen-containing catalysts of iron, manganese, copper and calcium or magnesium.

Oxley, Groombridge and Thomas[38] proposed the use of catalysts consisting of

an alkaline-earth oxide together with a weak acidic oxide, such as aluminum or zinc oxide, for the conversion of ethylene, aliphatic alcohols, aldehydes or esters by steam into aliphatic ketones. For example, a 60 to 70 per cent yield of acetone is stated to be obtained from steam and ethyl alcohol with a calcium oxide-zinc oxide "cement" catalyst at 465° to 480° C.

The preparation of acetone from acetylene is accomplished by treatment of a mixture of that hydrocarbon with steam under the influence of certain catalysts at relatively high temperatures. The acetone so obtained is usually accompanied by other products. The following materials are suggested as catalysts for the process: iron oxide,[39] thorium oxide or a double compound of thorium with alkali or alkaline-earth metals,[40] such as the double thorium-potassium carbonate $K_6Th(CO_3)_5$. The reaction temperature specified is about 450° C. and the conversion is usually not more than 40 per cent of the theoretical. According to the Holzverkohlungs-Industrie A.-G.,[41] the exothermic production of acetone from acetylene and steam at elevated temperatures is conveniently carried out along with the endothermic production of acetone from aliphatic alcohols of two or more carbon atoms per molecule. The raw material may be residual acetylene (containing uncondensed acetaldehyde, water, and acetic acid) obtained in the production of acetaldehyde from acetylene. Catalysts include the oxides of iron, zinc, or nickel with promoters such as alumina, barium carbonate, lime, or magnesia. Conversion of acetylene and excess steam into acetone at 275° to 725° C. in the presence of a composite catalyst of zinc chloride, iron and chromium oxides has also been described.[41a] Baur [41b] prepared ketones and aldehydes (propionaldehyde and acetone) by passing vapors of 1,2-oxides of hydrocarbons containing 2 to 4 carbon atoms at temperatures of 200° to 450° C. over a catalyst consisting of a halide of an alkaline earth metal. Lazier [42] used a mixture of a secondary alcohol and phenol to prepare acetone (mixed with cyclohexanol and cyclohexanone). The mixture was heated to 200° C. at a pressure of 500 pounds per square inch in the presence of a nickel catalyst.

Döderlein [42a] obtained acetone from oil resulting from the dry distillation of bituminous shale. After refining the oil with sulphuric acid the sludge was diluted with water and distilled. The ketones were recovered from the distillate.

PROPERTIES OF ACETONE

Acetone is a colorless mobile liquid having the following physical constants: b.p. 56.5° C.; m.p. —94.9° C.; d_4^0 0.81378; d_4^{15} 0.79705; d_4^{30} 0.77986; critical temperature 234.4° C.; latent heat of vaporization 125.28 Cals. per kgm. at 56.3° C. It is miscible in all proportions with water, alcohol, ether, many esters, and with many mineral and vegetable oils. It can be salted out of its aqueous solutions by calcium chloride. It is one of the most powerful solvents known and readily dissolves cellulose acetate, benzoate, nitrate and acetonitrate, ethyl cellulose, and many resins including glyceryl phthalate resins, crotonaldehyde resins, benzyl abietate, vinyl resin, elemi, rosin, ester gum, and copal. It only partly dissolves shellac, mastic, hard copals, and montan wax. Its solvent action on pitches and rubbers varies widely with the character of those products. A considerable number of azeotropic mixtures with other organic liquids are known, including one with methanol (13.5 per cent of methanol) boiling at 55.95° C., and one with chloroform (80 per cent chloroform) boiling at 64.7° C. The latter is remarkable in possessing a higher boiling point than either of its components.[43]

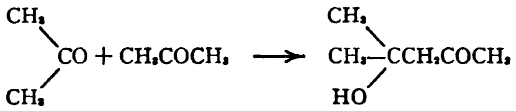
In chemical properties, acetone exhibits a high order of reactivity with many organic and inorganic substances. Only a few of the more important reactions will be discussed.

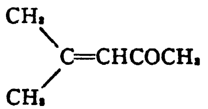
Iodine, chlorine, and bromine readily react with acetone in alkaline solution to form iodoform, chloroform, and bromoform, respectively, a reaction used for the manufacture of the two former materials.

When subjected to the action of alkalies acetone undergoes a condensation, very closely allied to the aldol condensation of aldehydes, which results in the formation of diacetone alcohol.[44]



Diacetone alcohol

Under the influence of dehydrating agents, diacetone alcohol loses the elements of water with the production of mesityl oxide.



This latter substance may be prepared directly from acetone by the action of anhydrous alkalies, such as lime (CaO), or other reconstituting agents, e.g., zinc chloride or hydrogen chloride.[44a] The condensation may even proceed a stage further to yield phorone.

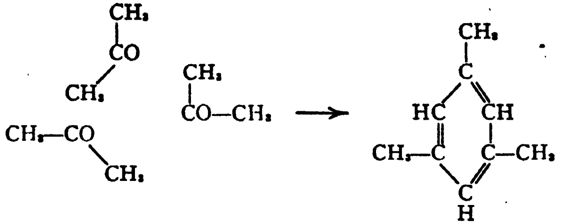
By heating acetone under pressure at 300° to 320° C. in the presence of zinc chloride, Ipatiev, Petrov and Ivanov[44b] obtained a mixture of unsaturated hydrocarbons, of which a large proportion was diisobutylene. Mesityl oxide and isophorone were also found in the products.

In the presence of concentrated sulphuric acid, three molecules of acetone unite to form a cyclic compound, mesitylene.



Both mesityl oxide and diacetone alcohol are of some industrial importance. *Diacetone alcohol,* an odorless, colorless liquid, may be used as a solvent for cellulose acetate in lacquers, since it yields films having a brilliant gloss. The fact that it rather easily hydrolyzes to acetone (a more volatile liquid) mitigates against its general use in the preparation of lacquers. It is also a solvent for cellulose nitrate, and for many resins, including the copals. It is considered non-toxic.

Diacetone alcohol can be made by treating acetone in alcoholic solution with sufficient alkali (sodium hydroxide) to give a reaction with cresol red but not with o-cresolphthalein.[45] Conant and Tuttle[46] obtained diacetone alcohol in yields of 71 per cent of the theoretical by boiling acetone with barium hydroxide. Calcium hydroxide,[47] concentrated sodium or potassium hydroxide solutions,[48] and magnesium amalgam[49] have also been recommended for this preparation. Ellis[50] treated acetone with about 0.01 to 0.02 per cent of alkali metal hydroxide at a temperature below 30° C., and Thomson[51] used a suspension of potassium hydroxide in acetone and benzene at room temperature. Nitriles, such as hydroxyalkylaminonitriles, can be prepared by the reaction of hydrocyanic acid on a mixture of a ketone and hydroxyalkylamines.[51a]

Mesityl oxide, a liquid of strong odor and b.p. 129.5° C., is insoluble in water. It is an excellent solvent for cellulose acetate and nitrate and would probably find extensive application in the lacquer industry but for its rather objectionable odor. Mesityl oxide may be condensed with aliphatic alcohols to yield ethers of diacetone alcohol.[52]

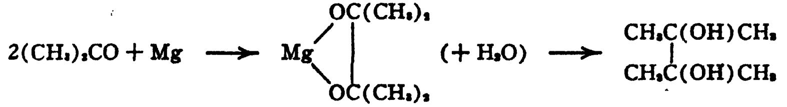
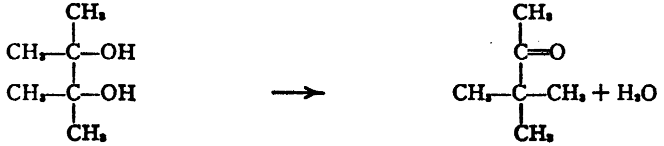
In addition to undergoing condensation of the aldol type, acetone may also yield pinacol.[53] This is accomplished by allowing acetone to react with magnesium amalgam, and then hydrolyzing the product. The reactions may be represented by



Distillation of the dry magnesium compound in a current of carbon dioxide gives pinacoline, acetone, isopropyl alcohol and mesityl oxide.

A further important step in this condensation, and one that is frequently used in organic synthesis, is the transformation of pinacol into pinacoline by mineral acids.



$$\begin{array}{c} CH_3 \\ | \\ CH_3-C-OH \\ | \\ CH_3-C-OH \\ | \\ CH_3 \end{array} \longrightarrow \begin{array}{c} CH_3 \\ | \\ C{=}O \\ | \\ CH_3-C-CH_3 \\ | \\ CH_3 \end{array} + H_2O$$

Pinacol *Pinacoline*

Passage of acetone vapors over red-hot magnesium yields a solid black mass, which on the addition of water gives hydrogen and allylene (methylacetylene).[54]

Another interesting condensation is that of olefins with acetone to yield high molecular weight ketones. This takes place best at high pressures (1000 to 3000 pounds) at temperatures of 250° to 350° C. in the presence of oxide catalysts such as those of nickel, zinc, chromium and vanadium.[55] Metallic chlorides such as zinc chloride or ferric chloride may be used as promoters. Ethylene and acetone, for example, at 1000 pounds pressure and 450° to 500° C. give propyl methyl ketone, and propylene and acetone at 2000 pounds pressure and 300° to 350° C. form butyl methyl ketone.

USES OF ACETONE

Two of the more important applications of acetone are in the manufacture of smokeless powder and celluloid. Acetone is used in making both cellulose acetate and nitrate solutions and in the production of certain kinds of artificial silk. Its solvent properties are utilized in the extraction or purification of a large number of organic products, such as fats and resins, and for numerous other purposes such, for example, as the scouring of wool. A solvent made by blending acetone with aromatic hydrocarbons, e.g., benzene or toluene, has been suggested as a dewaxing medium for lubricating oils.[56] The property of acetone as a solvent for acetylene is utilized on a large scale for the storing of that gas in steel cylinders for welding purposes. Acetylene is absorbed by a mixture of acetone and a porous earth and, in this form, can be safely handled even under considerable pressures, whereas acetylene normally explodes violently when compressed to a few atmospheres pressure. Acetone has been proposed in admixture with other liquids as a fuel for internal-combustion engines.[57] A mixture of acetone cyanohydrin and ethylene chloride in equal portions has been suggested as an insecticide.[57a]

Acetone is also the raw material for the manufacture of a number of synthetic organic chemicals, among which may be mentioned the drug, sulphonal, and the perfume, ionone, and it has been employed in the synthesis of indigo. Organic acid anhydrides have been prepared by treating organic acids and ketones, for example, acetic acid and acetone, at temperatures of about 600° C.[57b]

Duprat[57c] obtained several complex compounds of ferrocyanic and ferricyanic acid with ketones and aldehydes. The ferricyanic complexes decomposed when dried *in vacuo* over sulphuric acid, but ferrocyanic complexes could be purified and their exact composition determined.

The hydrogenation of acetone to isopropyl alcohol may be effected either by passing acetone and hydrogen over a catalyst at atmospheric or increased pressures or by conducting the hydrogenation in the liquid phase, i.e., by introducing hydrogen under pressure into a suspension of the catalyst in liquid acetone. Sabatier and Senderens[58] obtained an 85 per cent yield of isopropyl alcohol from acetone by hydrogenation over a nickel catalyst at 115° to 125° C. and observed that the reaction is very slow. Maxted[59] secured rapid hydrogenation to isopropyl alcohol by distilling acetone in a current of hydrogen at 100 atmospheres over a granulated nickel catalyst. For good yields a circulation method is desirable and the hydrogen should be in excess. Ipatiev's method of hydrogenation gives excellent yields of acetone at 100 to 200 atmospheres pressure in the presence of a nickel catalyst at 210° to 220° C. (at higher temperatures decomposition ensues). With a copper catalyst, higher temperatures (280° to 300° C.) are necessary to give a 65 per cent yield of acetone.[60] The usual industrial method of hydrogenation is to agitate acetone, carefully freed from catalyst poisons, with hydrogen under pressure in the presence of a nickel catalyst. Senderens and Aboulenc[61] found that the hydrogenation proceeded smoothly at 110° C. and 30 atmospheres in the presence of a nickel suboxide catalyst. Platinum black has also been used successfully as a catalyst.[62] The industrial method is further exemplified by Riedel,[63] who conducted the hydrogenation of acetone in the liquid phase at 100° C. and 15 atmospheres hydrogen pressure in the presence of a catalyst consisting of the mixed carbonates of nickel, cobalt, and copper in the molecular proportions, 60:30:10.

According to Adkins and Connor,[64] copper chromite is a very active catalyst

for the hydrogenation of organic substances. With this material, acetone is completely hydrogenated to isopropyl alcohol in the liquid phase at 150° C. under 100 to 150 atmospheres of hydrogen. For vapor-phase hydrogenation of acetone, Horsley[65] described a catalyst consisting of copper and silver with at least one oxide or hydroxide of a divalent metal. An alternative catalyst consists of a mixture of copper and nickel.[66]

Kirchov and Stepanov[66a] prepared isopropyl alcohol by electrolyzing acetone with a 15 per cent solution of sulphuric acid at 6 to 7 volts for 9 hours, using a mercury cathode and lead in 15 per cent sulphuric acid as an anode, the axis of the stirrer being passed through a porous vessel. The cathode liquid is neutralized with concentrated sodium hydroxide and distilled. A 33 per cent yield was obtained.

KETENE

The pyrolytic reactions of acetone are of considerable interest since it has been shown that the highly reactive substance ketene, $CH_2=CO$, is formed by the thermal treatment of acetone at high temperatures and high space velocities, generally in the absence of catalytic materials.

This type of compound was first made by Staudinger,[67] who produced diphenylketene, $(C_6H_5)_2C=CO$, by the action of zinc on diphenylchloroacetyl chloride dissolved in ether and described its properties. The substance reacted readily with oxygen to form an oxidation product (constitution undetermined) insoluble in benzene; with water, to give the corresponding acid; in non-aqueous solutions with hydrogen chloride, to yield the corresponding acid chloride; with alcohols, to form esters; and with ammonia and amines to form the amide and substituted amides, respectively.

Wilsmore[68] found that ketene, $CH_2=CO$, is produced by the action of a hot platinum wire on acetic anhydride, and also when an arc is made to burn beneath the surface of liquid acetic anhydride. He described the chemical properties of this substance, which were similar to those of diphenylketene. Ketene was also obtained by the action of a hot platinum wire on acetone vapors.[69] Other methods of preparation are the passage of acetone vapors through a combustion tube, made of silica, kept at a temperature above 740° C.,[70] and the dehydrogenation of acetaldehyde in the presence of nickel, copper or zinc.[71]

Ketene appears to be stable even at fairly high temperatures, and a 14 per cent yield was obtained by passing the vapors of acetone through a hard glass tube filled with porous earthenware and heated to 500° to 600° C. The decomposition of acetone appeared to take place in two stages: (1) at temperatures of about 500° to 600° C. ketene and methane are the principal products:

$$CH_3COCH_3 \longrightarrow CH_2{=}CO + CH_4$$

and (2) at higher temperatures, ketene is decomposed to yield carbon monoxide and ethylene:

$$2CH_2{=}CO \longrightarrow 2CO + C_2H_4$$

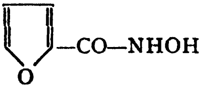
Some decomposition of ketene occurs at the lower temperature, particularly with low rates of gas flow.[72]

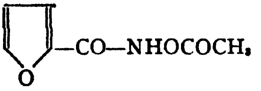
Hurd and Cochran,[73] using a method similar to that mentioned above, were able to increase the yield of ketene to 17.5 per cent by passing the vapors as they issued from the reaction tube through a condenser, thus immediately separating the acetone, as a liquid, from the gaseous ketene. They also showed that ketene is a very active acetylating agent, reacting with hydroxylamine to yield acethydroxamic acid,

$$CH_2{=}CO + NH_2OH \longrightarrow CH_3CONHOH$$

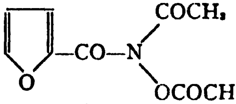
and with pyromucyl-hydroxamic acid to yield the mono- and diacetyl esters.



Pyromucyl-hydroxamic acid



Monoacetyl ester



Diacetyl ester

Ketene can also be prepared by passing the vapors of acetone through a copper tube heated to 650° to 670° C., and packed with copper turnings or those of other metals which melt above 700° C. The period of contact should be less than 5 seconds and the tube must be free from both iron and nickel.[74] An 80 per cent yield of ketene from acetic anhydride or acetone is stated to be obtained with the sulphates of chromium, manganese, aluminum, calcium, barium, strontium, magnesium, or silver or mixtures of these as catalysts[75] at a temperature of 635° C. These sulphates are said to function as "preventive catalysts" and counteract the tendency of the ketene to decompose. Ketenes may also be obtained by passing an aliphatic ketone or a secondary alcohol through a bath of fused metal or inorganic salts.[75a] Ott, Schröter and Packendorff[76] have reported a 50 per cent yield of ketene on passing the vapors of acetone over a heated tungsten filament.

In addition to the reactions previously mentioned ketene reacts with glacial acetic acid to yield acetic anhydride[76a] and with water to form acetic acid.[76b] De Simo,[77] in preparing mixed anhydrides, reacted a ketene with a carboxylic acid of a different number of carbon atoms and subsequently heated the resulting compound to rearrange it into anhydrides of the separate acids.

Ketene is gas at ordinary temperatures; it can be condensed to a liquid boiling at —56° C. and solidifying at —151° C.

HIGHER KETONES

The homologues of acetone are excellent solvents for many purposes, particularly in the cellulose lacquer industry where their higher boiling points make them superior to acetone. The high price and comparative scarcity of these ketones limit their application on a large scale. Provided they can be manufactured at a price not greatly exceeding that of acetone, there is a very wide field for higher ketones.[77a] As previously mentioned, the acetone homologues have heretofore been produced by the distillation of wood or by the dry distillation of the calcium salts of aliphatic acids, the latter being made principally by fermentation processes. The reaction between the vapors of esters and water at elevated temperatures in the presence of catalysts and a small amount of an oxygen-containing gas has been investigated as a method for the preparation of ketones.[78] The possibility of utilizing petroleum hydrocarbons as raw materials for the synthesis of these solvents is also receiving much attention.

Methyl ethyl ketone, $CH_3COCH_2CH_3$. This ketone is a colorless liquid of pleasant odor, boiling at 78.6° C. It is manufactured, together with acetone and other products, by the destructive distillation of wood. Mixtures of ketones are manufactured in France by the distillation of the calcium salts of lower fatty acids and sold under the name of Ketols.[79] The so-called *"Ethyl ketol,"* having a boiling range of 70° to 90° C., consists mainly of methyl ethyl ketone.

The oxidation of secondary butyl alcohol, made by the absorption of butene-1 and butene-2 in sulphuric acid and subsequent hydrolysis, offers a convenient method of preparing this ketone on a commercial scale. Oxidation may be effected in the presence of a silver catalyst. Catalytic dehydrogenation in the presence of copper also yields this ketone. Thus, Sabatier and Senderens [80] obtained methyl ethyl ketone from secondary butyl alcohol by using reduced copper heated to 160° to 300° C., and King [81] dehydrogenated this same alcohol in a similar manner at a temperature of 290° ± 5° C. The secondary butyl alcohol used in the latter work was obtained from butene-2, the yield of the ketone from the crude butene-2 being 70 per cent of the theoretical. The oxidation process, however, possesses advantages over dehydrogenation since the latter sometimes yields undesirable by-products. By the oxidation of secondary butyl alcohol with air in the presence of zinc oxide catalyst, Ottensooser [82] obtained a 93 per cent conversion into the ketone. In the industrial process, the air-alcohol mixture (in the vapor form) is conducted over a catalyst, heated initially to about 500° C. The heat of reaction is then sufficient to maintain the reaction chamber at the necessary temperature. Copper, either alone or alloyed with other metals such as zinc, is the catalyst generally employed.[83]

Another possible method for producing this ketone from petroleum hydrocarbons includes the reduction of methyl vinyl ketone made by the condensation of ethylene with acetyl chloride in the presence of anhydrous aluminum chloride.[84]

Methyl ethyl ketone is an excellent solvent and would replace acetone for many purposes if it could be prepared sufficiently cheaply and in quantity. Its lower vapor pressure renders it less liable than acetone to cause "blushing" in lacquers. This ketone is miscible with castor and linseed oils and with many hydrocarbons and will dissolve cellulose nitrate, ester gum, benzyl abietate, vinyl acetate, and cumarone and other resins. It is partially miscible with water (the ketone dissolves 90 per cent of its weight at 20° C. and water dissolves 24 per cent of its weight of the ketone) with which it forms a constant-boiling mixture (containing 11.4 per cent of water) boiling at 79.6° C. Methyl ethyl ketone is utilized as a solvent, mainly for cellulose esters in lacquers, although it is also used to a very limited extent for the manufacture of certain high grade organic products, such as the perfume, methylionone, and the drug, trional.

Di-n-propyl ketone (Butyrone), $CH_3CH_2CH_2COCH_2CH_2CH_3$. This ketone is available in an impure form under the name of amyl ketol, which is manufactured by the dry distillation of calcium butyrate. The calcium butyrate necessary for the process is said to be made by fermentation of saccharified wood in the presence of calcium carbonate. Dipropyl ketone may be produced by interaction of butyraldehyde with steam at 400° to 500° C. in the presence of nickel or cobalt and iron, promoted with an alkaline-earth compound.[85]

In the pure state butyrone boils at 143.5° C. and has d_4^{20} 0.820. It is a solvent for both cellulose nitrate and acetate and also for rubber, natural and synthetic resins of many types, and for linseed and castor oils. It combines these solvent properties with freedom from toxicity under normal working conditions, and a pleasant sweetish odor.

Table 89 summarizes the boiling points and densities of some simple aliphatic ketones.

TABLE 89.—*Aliphatic Ketones.*

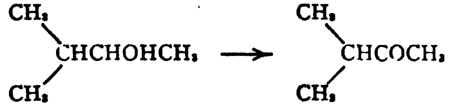
Name	Formula	B.P. ° C. (760 mm.)	d_4^t
Diethyl ketone	$C_2H_5COC_2H_5$	101.1	0.821 (15° C.)
Methyl n-propyl ketone	$CH_3COC_3H_7$	101.8	0.808 (20° C.)
Methyl isopropyl ketone	$CH_3COCH(CH_3)_2$	92.4	0.803 (20° C.)
Methyl n-butyl ketone	$CH_3COC_4H_9$	127.4	0.830 (0° C.)
Methyl n-amyl ketone	$CH_3COC_5H_{11}$	151–152	0.813 (20° C.)

POSSIBLE METHODS OF MANUFACTURE OF THE HIGHER ALIPHATIC KETONES FROM PETROLEUM DERIVATIVES. THE OXIDATION OF SECONDARY ALCOHOLS

All the higher secondary alcohols, amyl, hexyl, and heptyl included, may be converted into ketones by catalytic oxidation with air. These secondary alcohols may be manufactured by methods discussed in Chapter 17 from the low-boiling olefin hydrocarbons of cracked gasoline. Ottensooser,[86] for example, reported that secondary octyl alcohol may be converted into the corresponding ketone (in a yield of 79 per cent of the theoretical) by oxidation with air in the vapor phase at 330° to 340° C. in the presence of a zinc oxide catalyst. In this way it should be possible to find an outlet for the higher secondary alcohols obtained as byproducts of the preparation of secondary butyl alcohol from cracking-gas fractions. By catalytic oxidation, pentanol-2 should yield methyl n-propyl ketone

$$CH_3CH_2CH_2CHOHCH_3 \longrightarrow CH_3CH_2CH_2COCH_3$$

and 3-methylbutanol-2, methyl isopropyl ketone.



$$(CH_3)_2CHCHOHCH_3 \longrightarrow (CH_3)_2CHCOCH_3$$

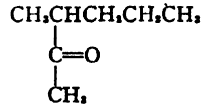
APPLICATION OF THE FRIEDEL-CRAFTS REACTION TO PARAFFINIC AND CYCLOPARAFFINIC HYDROCARBONS

A promising development in the realm of hydrocarbon chemistry is the extension of the Friedel-Crafts reaction, which was formerly considered applicable only to aromatic hydrocarbons, to olefins and also to paraffins and cycloparaffins. Not only can organic acid chlorides condense with these hydrocarbons in the presence of condensing agents (e.g., $AlCl_3$), but also with carbon monoxide under pressure, to yield ketones. Descriptions of these condensations have been supplied by Hopff.[87]

The condensation of n-pentane with acetyl chloride was found to take place readily in the presence of aluminum chloride in the cold and the product was proved to be 2-acetylpentane (asymmetrical methyl n-propyl acetone), a liquid (b.p. 136°–140° C.) possessing the constitution

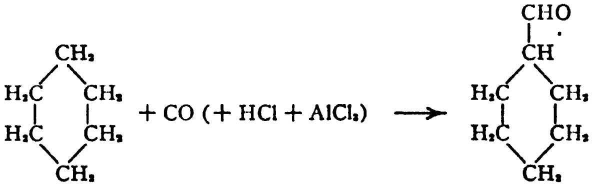


$$CH_3\underset{\substack{|\\ C=O\\ |\\ CH_3}}{C}HCH_2CH_2CH_3$$

From 2500 cc. of n-pentane and 800 grams of acetyl chloride in the presence of 1250 grams of finely powdered anhydrous aluminum chloride Hopff obtained, after decomposition with water, 120 grams of the above ketone together with about 180 grams of a black viscous oil which was not further investigated. The yield of ketone is therefore very poor.

Treatment of 2500 cc. of cyclohexane with 1250 grams of aluminum chloride and 800 grams of acetyl chloride in a similar manner, yielded 800 grams of a yellowish oil volatile with steam, together with 250 grams of a non-volatile dark-colored residue. Fractionation of the former (volatile) liquid yielded 410 grams of a colorless liquid of aromatic odor (b.p. 160°–180° C.) consisting mainly of cyclohexyl methyl ketone. The procedure can be applied also to methane, ethane, and propane but rather less satisfactorily.

Hopff also investigated the reaction of carbon monoxide, under a pressure of 150 atmospheres, with paraffins and cycloparaffins and obtained aldehydes and ketones. Eight hundred grams of cyclohexane and 500 grams of anhydrous aluminum chloride in a 2 liter autoclave with 10 atmospheres of dry hydrogen chloride and 150 atmospheres of carbon monoxide were allowed to stand for 48 hours at ordinary temperature. After decomposition with ice, 135 grams of a liquid volatile with steam was formed. This liquid was extracted with 5 per cent aqueous caustic soda and then distilled, finally yielding about 50 grams of hexahydrobenzaldehyde, b.p. 166°–167° C.

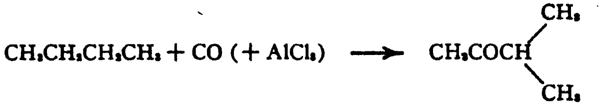


When 100 grams of n-butane were allowed to react with carbon monoxide in the presence of 100 grams of aluminum chloride under a pressure of 130 atmospheres at ordinary temperature (20° C.) for 20 hours, the yield of methyl isopropyl ketone was about 6 grams together with a considerable quantity of other products. In the reaction between carbon monoxide and n-butane a branched-chain ketone is formed:

---

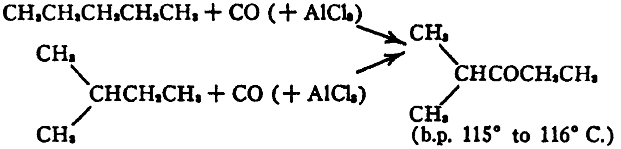
[87] *Ber.*, 1931, **64**, 2739. British Patent 327,411, 1928; *Brit. Chem. Abs.* **B**, 1930, 602; French Patent 671,241, 1928; *Chem. Abs.*, 1930, **24**, 2137; U. S. Patent 1,801,350, Apr. 21, 1931; *Chem. Abs.*, 1931, **25**, 3358, all patents assigned to I. G. Farbenindustrie A.-G.

For similar application of the Friedel-Crafts reaction see Schaarschmidt, French Patent 42,410, 1933; *Chem. Abs.*, 1933, **27**, 4813; French Patent 735,786, 1931; *Chem. Abs.*, 1933, **27**, 991; British Patent 388,734, 1933; *Chem. Abs.*, 1933, **27**, 4538; Mark, Dunkel and Roell, U. S. Patent 1,899,582, Feb. 28, 1933; assigned to I. G. Farbenindustrie A.-G.; *Chem. Abs.*, 1933, **27**, 2961; I. G. Farbenindustrie A.-G., British Patent 391,600, 1933; *Brit. Chem. Abs.* **B**, 1933, 377; Nenitzescu and Cantuniari, *Ber.*, 1932, **65**, 807. See also von Braun, *Ber.*, 1931, **64**, 2869.



$$CH_3CH_2CH_2CH_3 + CO\ (+ AlCl_3) \longrightarrow CH_3COCH(CH_3)_2$$

Ethyl isopropyl ketone was obtained by treating either normal- or iso-pentane with carbon monoxide under pressure in the presence of aluminum chloride. The reactions may be summarized in the following manner:

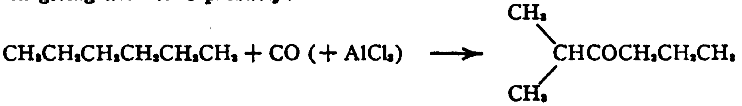


$$CH_3CH_2CH_2CH_2CH_3 + CO\ (+ AlCl_3) \longrightarrow (CH_3)_2CHCOCH_2CH_3$$
$$(CH_3)_2CHCH_2CH_3 + CO\ (+ AlCl_3) \longrightarrow (CH_3)_2CHCOCH_2CH_3$$

(b.p. 115° to 116° C.)

The yield of ethyl isopropyl ketone in either case was, however, poor and relatively large amounts of other products were formed including fatty acids and resins. Thus, by working up the products of the reaction of 108 atmospheres of carbon monoxide on 1 kilogram of n-pentane and 750 grams of aluminum chloride at 50° C. (for five hours), only about 250 grams of crude ethyl isopropyl ketone were secured. Among the acidic products, α-methylvaleric acid was identified. From 1 kilogram of isopentane under similar conditions, only 70 grams of pure ketone were obtained.

Treatment of 1 kilogram of n-hexane with 1 kilogram of aluminum chloride and with carbon monoxide (118 atmospheres pressure) at 50° to 60° C. for 18 hours yielded the following products: 350 grams of unchanged hexane, 520 grams of an oil volatile with steam, and 270 grams of non-volatile oil. The steam-distilled oil was extracted with alkali (acidification of this alkaline extract gave 62 grams of carboxylic acids (b.p. 195° to 240° C.) besides small amounts of higher acids) and distilled to yield 180 grams of liquid boiling up to 160° C. Redistillation gave 18 grams of a liquid (b.p. 135° to 137° C.) which was considered to be n-propyl isopropyl ketone. The reaction giving ketones is probably:



$$CH_3CH_2CH_2CH_2CH_2CH_3 + CO\ (+ AlCl_3) \longrightarrow (CH_3)_2CHCOCH_2CH_2CH_3$$

Although the results of Hopff are of interest, the reported yields of the purified ketones are far too small for the reaction to serve as a technical method for their production. Moreover, large proportions of the original hydrocarbons are converted into aliphatic acids and higher condensation products. In spite of these defects, however, it may be possible to modify the working conditions so as to reduce, in part at least, the formation of by-products.

The direct combination of phosgene with hydrogen and paraffin hydrocarbons to yield either aldehydes or ketones was described by Fohlen.[88] He proposed to effect these combinations in the presence of catalysts consisting of finely divided metals, or their oxides or salts. The following reactions are said to occur between phosgene and hydrogen and methane:

$$COCl_2 + 2H_2 \longrightarrow HCHO + 2HCl$$
$$2CH_4 + COCl_2 \longrightarrow CH_3COCH_3 + 2HCl$$
$$CH_4 + H_2 + COCl_2 \longrightarrow CH_3CHO + 2HCl$$

---

[88] French Patent 680,586, 1928; *Chem. Abs.*, 1930, 24, 3799.

KETONES FROM OLEFIN HYDROCARBONS

The condensation of the simple monolefins with organic acid chlorides at low temperatures in the presence of aluminum chloride (or other Friedel-Crafts condensing agents) leads to the production of alkyl vinyl ketones of the general formula

$$R^1R^2C{=}CR^3COC_nH_{2n+1}$$

in which R^1, R^2 and R^3 are hydrocarbon radicals or hydrogen. A discussion of this condensation is given in Chapter 24, in which it is pointed out that unstable chloro ketones are formed as intermediates. The yields of vinyl alkyl ketones appear to be good and the process offers a way for the preparation of the higher aliphatic ketones of four and more carbon atoms. The reduction of the alkyl vinyl ketones to saturated ketones involves the hydrogenation of an unsaturated linkage under such conditions that the carbonyl group remains unattacked.

$$R^1R^2C{=}CR^3COC_nH_{2n+1} + H_2 \longrightarrow R^1R^2CHCHR^3COC_nH_{2n+1}$$

The direct alkylation of ketones by olefins was suggested by Brown.[89] The reaction is carried out at temperatures of 250° to 500° C., under pressures of more than 50 atmospheres in the presence of catalysts such as zinc or chromium oxides and zinc chloride. An example of such an operation is the synthesis of propyl methyl ketone from ethylene and acetone. The vapors of acetone and ethylene, in approximately molecular proportions, are slowly led (under 1000 pounds pressure) over a zinc oxide-chromium oxide catalyst maintained at 450° to 500° C. On cooling the exit gases to 0° to 15° C. a liquid mixture of ketones, acetone and ethylene is obtained. The propyl methyl ketone is separated by fractional distillation.

An indirect method of transforming olefins into ketones (or aldehydes) is their conversion into the corresponding oxides followed by isomerization of the latter compounds into substances containing the :CO group. Thus, the isomerization of trimethylethylene oxide to methyl isopropyl ketone in the presence of alumina at 200° to 300° C. was observed by Ipatiev and Leontowitsch.[90] The isomerization of olefin oxides to aldehydes and ketones is effected by heating in the presence of catalysts, such as magnesium pyrophosphate or copper sulphate, with or without the addition of metal oxides, hydroxides, or carbonates, at temperatures of 180° to 300° C.[91]

Of the cyclic ketones, cyclohexanone and the three isomeric methylcyclohexanones are of technical importance. Although they are produced on a large scale from phenol and the cresols, respectively, yet they should be considered as derivatives of naphthene, or petroleum, hydrocarbons.

Cyclohexanone,  $H_2C\begin{matrix}CH_2CH_2\\ \\ CH_2CH_2\end{matrix}CO$, is prepared by the oxidation or catalytic dehydrogenation of cyclohexanol which in turn may be prepared by the hydrogenation of phenol. If the hydrogenation of phenol is carried out at high temperatures the cyclohexanol initially formed undergoes thermal dehydrogenation to cyclohexanone.[92] The oxidation of cyclohexanol with air in the presence of copper gives an excellent yield of this cyclic ketone.

---

[89] U. S. Patent 1,757,830, May 6, 1930; assigned to Commercial Solvents Corp.; *Chem. Abs.*, 1930, 24, 3247.

[90] *Ber.*, 1903, 36, 2016.

[91] I. G. Farbenindustrie A.-G., British Patent 331,185, 1929; *Brit. Chem. Abs.* B, 1930, 939. British Patent 354,388, 1930; *Brit. Chem. Abs.* B, 1932, 12.

Pure cyclohexanone is a colorless oil (b.p. 156.6° to 156.8° C. and $d^{15.8}_{4}$ 0.9503) and is an excellent solvent for cellulose nitrate and for many natural and synthetic gums and resins. Solutions of cellulose nitrate in this solvent are less viscous than those in ethylene glycol monoethyl ether and exhibit a high tolerance to toluene dilution.[93]

The methylcyclohexanones are prepared by similar methods. A mixture of the three isomeric ketones is marketed as an industrial solvent. The methylcyclohexanones are colorless oils of peppermint-like odor, and possess solvent properties toward cellulose nitrate, yielding solutions which possess rather high viscosities and a high tolerance to toluene dilution.

Another cyclic ketone which may ultimately be produced from cyclopentane of petroleum origin is cyclopentanone,  , a highly reactive ketone (b.p. 129° C. and d^{0}_{20} 0.948). It is obtained in small amounts by the destructive distillation of wood but, on account of its scarcity, as yet has no industrial application. The possibility of making ketones, containing the cyclopentyl ring, from the naphthenic acids of petroleum is discussed in Chapter 48.

---

[92] Such reactions are discussed by Ellis, "Hydrogenation of Organic Substances," D. Van Nostrand Co., 1930.

[93] Durrans, "Solvents," Chapman and Hall, London, 1930.

Chapter 19

Sulphur and Sulphur Compounds in Petroleum and Its Distillates. Their Occurrence, Chemical Properties and Possible Applications

The sulphur content of crude petroleum oils from different localities varies over a wide range. For example, the Pennsylvania, Baku, and Rumanian oils contain 0.2 per cent sulphur or less, while those from Ohio, West Texas and California contain from 0.5 per cent to 1.5 per cent or higher. Some California oils have been reported to contain as much as 4 per cent sulphur and many Mexican oils contain as much as 5 per cent.[1] When the crude oil is distilled, under conditions which do not permit cracking of the oil, it is generally found that the sulphur content of the various fractions increases with the boiling range, the residues possessing the highest percentage of sulphur. Curves obtained by plotting the sulphur content against the boiling range of close-cut fractions exhibited a series of rising peaks.[2]

Practically all of the simpler types of organic sulphur compounds have been identified in petroleum oils;[3] these include carbon disulphide, mercaptans, thioethers, thiophenes, thiophanes, organic disulphides and polysulphides, elemental sulphur, and compounds containing both sulphur and oxygen. Hydrogen sulphide is also associated with many high sulphur crude oils. Most of the individual sulphur compounds so far isolated have been found in relatively low-boiling fractions. Of the organic sulphides occurring in oils boiling above 230° C. diphenyl sulphide appears to be the only one which has been identified.

From the refiner's view the two principal objections to the presence of sulphur compounds in distillates, particularly the gasoline and kerosene fractions, are their corrosive properties and their odor. Hydrogen sulphide and mercaptans produce the most objectionable odors, and in both instances this can be easily remedied. Hydrogen sulphide is removed by washing the distillates with dilute solutions of alkalies, either sodium hydroxide or sodium carbonate. The mercaptans, while not so easily removed, can be converted to disulphides (sweetening) which impart a less disagreeable odor to petroleum distillates than the original substances. In addition to their unpleasant odor, mercaptans are strong positive catalysts for gum formation, particularly in gasolines made by cracking.[4]

Corrosion by sulphur compounds may be divided into two types: that caused by these compounds themselves when the petroleum distillates containing them

are allowed to remain in contact with metals for some time, and that resulting from the formation of sulphur dioxide (and subsequently sulphuric acid) when the distillates are used in internal-combustion engines.

With respect to the first type of corrosion, Schmidt[5] found that the order of decreasing activity is: mercaptans,[6] elemental sulphur, alkyl sulphates, alkyl sulphides, disulphides, sulphur oxides, carbon disulphide and thiophenes. Heat increases the corrosive action of all of these, and water especially increases the corrosive action of alkyl sulphates by their hydrolysis to yield sulphuric acid. In general, those sulphur compounds which tend to ionize, such as mercaptans, are the most corrosive.

Opinions differ widely as to the amount of sulphur permissible in distillates, such as gasoline for use in internal-combustion engines. For example, Diggs[7] concluded from his experiments that 0.1 per cent sulphur is probably a fair allowable upper limit to avoid excessive corrosion of wrist pins, pistons and rings. This corrosion he explained in the following manner: during combustion of the fuel, sulphur dioxide, water vapor and carbon dioxide are formed. The sulphur dioxide reacts with the condensed water vapor and oxygen of the air to form sulphuric acid, and the sulphuric acid in turn attacks the metallic parts. Mougey[8] on the other hand contended that, with elimination of the condensation of water vapor by crankcase ventilation and thermostatic control of the water jacket temperatures, sulphur corrosion is so greatly reduced as to allow the use of fuels containing as much as 0.25 per cent sulphur. Rackwitz and von Philippovich[9] have also reported that ventilators, thermostats and oil filters permit the use of a fuel containing 0.25 to 0.35 per cent sulphur. Egloff, Lowry and Truesdell[10] reported that the United States is the only country, so far as is known, in which a limit is imposed on the sulphur content of gasoline, and that in Europe, where no limit is set, corrosion due to sulphur is practically unknown.

In this chapter the sulphur derivatives of petroleum are considered with respect to their chemistry, isolation and possible utilization. Refining methods which have as their object primarily the elimination or removal of sulphur compounds from petroleum distillates are mentioned only when they illustrate specifically some of the chemical properties of these sulphur derivatives. More work along the lines indicated has been done with the simpler sulphur derivatives in petroleum, such as elemental sulphur, hydrogen sulphide and mercaptans, than with the more complex compounds, for example, the thioethers and thiophene. For this reason the chemistry of the former is discussed in more detail than that of the latter.

HYDROGEN SULPHIDE

Hydrogen sulphide, which is a gas at ordinary temperatures and pressures, is frequently found in crude petroleum or its distillates, particularly in high sulphur crudes and their derivatives. It is generally more soluble in petroleum hydrocarbons than in water. Table 90 gives the solubility of hydrogen sulphide in water and a number of hydrocarbons at 20° C., the figures representing the number of volumes of the gas dissolved in a unit volume of solvent.[11]

TABLE 90.—*Solubility of Hydrogen Sulphide in Water and Some Organic Solvents.*

Solvent	Volumes of H_2S Dissolved per Unit of Solvent at 20° C.
Water	2.905
Hexane	6.30
Octane	6.80
Dodecane	5.71
Cyclohexane	7.50
Benzene	15.68
Toluene	16.90

The presence of hydrogen sulphide in the various distillates is undesirable because of danger to workingmen (it is toxic), corrosion of equipment, fires caused by the rapid oxidation of the iron sulphide formed by hydrogen sulphide corrosion, and lastly the oxidation of hydrogen sulphide itself (by the oxygen of the air) to water and elemental sulphur.

The uses of hydrogen sulphide, outside of the laboratory, are rather limited. Its salts, however, such as sodium sulphide, have been used as aids in the dyeing of cotton fiber with sulphur dyes, as reducing agents or otherwise in the preparation of dyestuffs, as depilatories for hides and skins, and as denitrating agents for artificial silk.

One method of extracting hydrogen sulphide from petroleum is by washing the various fractions with dilute alkaline solutions. It may be done also by adding the alkaline solution to the distillate stream as the latter comes from the fractionating column on the still to the run-down tank.[12] Such processes are based on the fact that hydrogen sulphide possesses acidic properties and reacts with bases to form compounds according to the following reactions:

$$NaOH + H_2S \longrightarrow NaHS + H_2O$$
$$NaHS + NaOH \longrightarrow Na_2S + H_2O$$

As pointed out later the alkaline solutions used in the extraction of hydrogen sulphide from some distillates also dissolve a part of the low-boiling mercaptans. These mercaptans can be recovered by the distillation of the alkaline solutions.

For refining petroleum distillates several modifications of this method have been suggested. For example, solutions of a mixture of sodium bicarbonate and carbonate[13] and of sodium tetrathionate[14] have been recommended for the removal of hydrogen sulphide. In the first instance the reagent, after use, may be regenerated by aeration in the presence of a small quantity of either nickel or cobalt sulphide to serve as a catalyst. It has been reported that when large quantities of hydrogen sulphide are to be removed the addition of zinc sulphate to caustic soda solution gives better results.[15]

Another reagent proposed for the removal of hydrogen sulphide is brucite, or magnesium hydroxide.[16] The gasoline, or other petroleum distillate, is agitated with a suspension of this base in water, and hydrogen sulphide is removed as magnesium hydrosulphide, according to the equation:

$$Mg(OH)_2 + 2H_2S \rightleftharpoons Mg(SH)_2 + H_2O$$

[14] Rosenstein, U. S. Patent 1,832,325, Nov. 17, 1931; *Chem. Abs.*, 1932, 26, 839.
[15] *Refiner*, Dec. 1931, 87.
[16] Gardner and Higgins, *Ind. Eng. Chem.*, 1932, 24, 1140; Higgins, *Nat. Pet. News*, 1933, 25 (15), 26; *Chem. Abs.*, 1933, 27, 3594; *Oil and Gas J.*, 1933, 31 (50), 10.

At ordinary temperatures this reaction proceeds mainly toward the right, while at elevated temperatures it is reversed, affording an easy method of regenerating the spent brucite. As neither the hydroxide nor the hydrosulphide of magnesium is very soluble in water, it is often necessary to extract several times to free a distillate of a high percentage of hydrogen sulphide. This reagent has been used successfully in the extraction of hydrogen sulphide not only from distillates, but also from still gases, natural gas, and crude oils.

Several methods are available for the removal of hydrogen sulphide from still gases. One method is to wash the gas with a solution of sodium or potassium carbonate.[17] The spent carbonate solution can be regenerated afterwards by passing carbon dioxide through it, to expel the hydrogen sulphide, followed by heating, to convert the bicarbonates to carbonates. In the Koppers [18] process the alkaline solution, sodium carbonate or phosphate, is regenerated by adding a sulphide, such as nickel sulphide, and oxidizing the solution with air. Free sulphur rises to the surface of the solution and may be skimmed off. Sodium carbonate solutions, used for the absorption of hydrogen sulphide, may be regenerated by heating and aeration,[19] or by passage over iron compounds,[20] such as the oxide, carbonates, or basic carbonate. Suspensions of the hydroxides, oxides, carbonates or basic carbonates of magnesium, barium, calcium or strontium in an alkaline solution may be employed as the absorbing media.[21] Other solvents suggested for washing the gases to absorb hydrogen sulphide are solutions of a compound of ammonium thiosulphate and sulphur dioxide,[22] a mixture of sulphites and bisulphites,[22a] ammonium tetrathionate and thiosulphate,[22b] potassium hydroxide and boric acid,[22c] and alkaline solution of potassium ferricyanide,[23] lime water,[23a] aqueous ammonia,[23b] aqueous sulphur dioxide,[23c] or potassium phosphate.[23d] Absorption of hydrogen sulphide with water alone has been employed.[23e] Mann and Lebo [23f] used a suspension of iron oxide in caustic soda solution and regenerated the mixture, which had been converted to iron sulphide suspended in an alkaline solution, by blowing with air. Free sulphur is formed and removed in the foam produced during oxidation. Klempt and Brodkorb[23g] recommended ferric hydroxide sludge in aqueous ammonia for this purpose.

Aqueous solutions of triethanolamine, or of a mixture of ethanolamines, are employed for the removal of hydrogen sulphide from gases.[24]

Activated charcoal[24a] was recommended for the adsorption and catalytic oxidation of hydrogen sulphide. Ferric oxide and hydroxide,[24b] silica gel,[24c] or bauxite,[24d] and a metallic oxide (e.g., iron oxide) have been suggested for the same purpose. The capacity of ferric oxide for removing hydrogen sulphide is increased by the addition of activated carbon.[24e] Nickel oxide, together with an oxygen-transferring element of Groups IV to VI of the periodic table and 10 per cent of lead or bismuth, has been employed.[24f] Another method is the preferential oxidation of hydrogen sulphide and organic sulphides, by a mixture of metallic oxides such as those of copper and chromium, or copper, chromium and uranium.[24g]

SOME APPLICATIONS OF HYDROGEN SULPHIDE

The complete removal of hydrogen sulphide from gaseous mixtures, which are to undergo further treatment, is oftentimes undesirable. For example, in the treatment of hydrocarbon gases with steam at 1000° C. in the presence of a chromium catalyst to yield hydrogen and carbon monoxide, the efficiency of the catalyst is said to be increased if about one per cent of hydrogen sulphide, or other gaseous sulphur compounds, are present in the reaction mixture.[25]

Under certain conditions hydrogen sulphide will react with gaseous hydrocarbons, particularly at high temperatures. For example, Wheeler and Francis[26] have reported that when a gas containing methane, ethane and propane is mixed with 12.5 per cent hydrogen sulphide and the mixture is passed at the rate of 250 reciprocal minutes through a reaction chamber heated to 1200° C., both carbon disulphide and benzene are obtained. The yields of these substances are about 0.6 gallon of carbon disulphide and 0.3 gallon of benzene per 1000 cubic feet of gas. Olefinic gases and gases normally containing hydrogen sulphide or other sulphides, such as natural gas, are said to react in a similar manner.

Ethylenic hydrocarbons, such as ethylene, propylene, butylene or isoamylene, react with hydrogen sulphide at 650° to 725° C. in the presence of silica gel.[27] A variety of products are obtained, including hydrogen, methane, ethylenic and saturated hydrocarbons, aromatics, mercaptans, thioethers, thiophene and its homologues and carbon bisulphide. With respect to the formation of sulphur compounds, the mercaptans are formed by the interaction of the unsaturated hydrocarbons and hydrogen sulphide. Decomposition of the mercaptans yields thioethers, and the latter in turn give thiophene and its homologues. Butyl sulphide or mercaptan in the presence of silica gel at 700° C. was converted into thiophene.[28] The proportion of carbon bisulphide was greater at the higher temperatures.

Acetylene and hydrogen sulphide react at a temperature of 320° C. in the presence of bauxite to yield a product, containing about 30 per cent sulphur, from which almost pure thiophene may be obtained by fractional distillation. In the presence of a catalyst consisting of nickel hydroxide and cement at a temperature of 300° C. these same reactants yield a product high in sulphur from which mercaptans, thiophene and methyl thiophene may be separated by fractionation.[29]

ELEMENTAL SULPHUR

The presence of elemental sulphur in various petroleum distillates probably results from the decomposition of complex sulphur compounds during distillation as well as the oxidation of hydrogen sulphide. It no doubt also occurs naturally in high sulphur crude petroleums and comes over, to some extent at least, during the distillation of the various fractions. As elemental sulphur exerts a high corrosive action on various metals [30] its removal from petroleum distillates is highly desirable.

Petroleum and its distillates cannot be regarded in any sense as a source of raw elemental sulphur for two reasons: first, because of the very small percentage of it actually present, and, second, because of the difficulties of extracting it as such. Furthermore, abundant natural sources of sulphur are available from which this element is obtained much more economically than by any procedures so far suggested to recover it from petroleum. The discussion of sulphur extraction from petroleum oils is therefore limited to its removal from these oils on account of its corrosive properties.

Several methods for the removal of elemental sulphur are based on its reactions with alkali or alkaline earth sulphides to form the corresponding polysulphides. Sodium sulphide (Na_2S), for example, yields a series of polysulphides varying in composition from Na_2S_2 to Na_2S_5. Another reaction often employed is that between elemental sulphur and soluble lead mercaptides, whereby lead sulphide and organic disulphides are formed. This reaction is known as *sweetening* and is discussed in more detail later.

Cobb [31] has suggested heating the oil with caustic alkali, such as sodium hydroxide, or calcium hydroxide, and hydrogen sulphide. Treating oil containing both hydrogen sulphide and sulphur with an alkaline solution and heating [32] has also been proposed. In both instances the alkali sulphide first formed reacts with elemental sulphur to form the alkali polysulphide. Calcium sulphide may be used [33] in place of the alkali. Youtz and Perkins [34] used a concentrated solution of sodium sulphide for the same purpose.

The use of "spent doctor" (sodium plumbite solution which has been used in the treatment of "sour" distillates) has been proposed by Simpson.[35] The effectiveness of this reagent is probably due to the sodium sulphide, or mercaptides, produced in the treatment of the distillate. Sodium sulphide reacts with sulphur to form water-soluble polysulphides, and sodium mercaptides with the sulphur yield sodium sulphide and organic disulphides.

---

[28] Malisoff and Marks (*Ind. Eng. Chem.*, 1931, 23, 1114) report that mercaptans are thermally decomposed at temperatures of about 475° C. to yield hydrogen sulphide and the corresponding olefin.

[33] Cobb, U. S. Patent 1.357,225, Nov. 2, 1920; *Chem. Abs.*, 1921, 15, 311.

[34] *Ind. Eng. Chem.*, 1927, 19, 1247.

Wendt and Diggs[36] have pointed out that some sour distillates contain sufficient elemental sulphur, in addition to mercaptans, to precipitate lead sulphide immediately on agitating with sodium plumbite solution and to sweeten the distillate without the addition of sulphur. This, of course, removes the elemental sulphur. Such a process may also be applied by mixing a distillate containing mercaptans with one containing elemental sulphur and then agitating the mixture with sodium plumbite solution.

Vesselovsky and Kalichevsky[37] suggested the use of potassium or sodium hydroxide dissolved in organic solvents such as absolute ethyl or isopropyl alcohols, absolute ether, or 91 to 98 per cent isopropyl alcohol. Of the two alkalies, potassium hydroxide reacts the more rapidly to produce potassium thiosulphate, polysulphides and water. The following reaction has been suggested by these investigators as taking place initially:

$$6KOH + 6S \longrightarrow K_2S_2O_3 + 2K_2S_2 + 3H_2O$$

This is very probably followed by reaction of potassium disulphide with elemental sulphur to yield the trisulphide and possibly higher sulphides.

The use of an alkali sulphide dissolved in a non-aqueous solvent (for example, mono- or di-hydric alcohols, ketones or epichlorohydrin) was suggested by Malisoff.[38] The alkali sulphide (or polysulphide) in an organic solvent (methanol) is stated to have a reducing action on organic disulphides.

It appears possible not only to remove elemental sulphur but other types of sulphur compounds as well in a single operation. For example, Dormon[39] proposed treating gasoline, or higher distillates, with nickel or other metals in rotating cells, and Bruzac[40] suggested distilling the heavier oils (at temperatures not exceeding 500° C.) in the presence of metals (iron, copper or nickel). Washing dry, finely ground potassium hydroxide with gasoline is reported by Wilson[41] to reduce materially its sulphur content. Faught[42] described a process in which gasoline vapors are treated with sodium vapors, which not only remove sulphur with the formation of sodium sulphide but gum-forming compounds as well. Treatment of the distillates with lead, mercury, or copper, or their amalgams or oxides at temperatures below 80° C. was recommended by Mossgraber.[43]

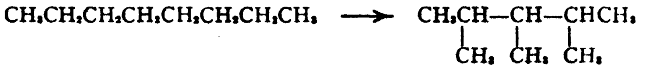
REACTION OF SULPHUR WITH PARAFFIN HYDROCARBONS

As previously pointed out, elemental sulphur may exist as such in crude petroleum or may be formed by the decomposition of complex organic sulphur compounds during the distillation processes. At such temperatures, or at higher temperatures as in cracking operations, elemental sulphur itself reacts with petroleum hydrocarbons to yield various sulphur compounds. A review of the possible reactions which may take place should therefore be of interest.

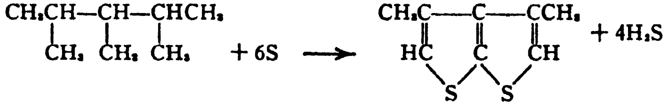
The paraffin hydrocarbons of lower molecular weights generally react very slowly, if at all, with sulphur. Spanier[44] has shown that n-hexane and sulphur do not react appreciably when heated for 24 hours at 210° C. At 300° to 350° C. and over long periods of heating, n-butane and n-heptane yielded, with sulphur, some thiophene and thiophene derivatives, respectively. At higher temperatures, however, reaction does take place as Fletcher, Wheeler and McAulay[45] have found that methane at 1100° C. reacts with sulphur vapors to form carbon disulphide. They also stated that at such high temperatures hydrogen sulphide behaves in the same way as sulphur vapors.

On heating n-octane with sulphur in sealed tubes at 270° to 280° C. Friedmann[46] obtained small quantities of a thiophene, $C_8H_{12}S$, and of a thiophthen, $C_8H_8S_2$. The formation of such cyclic compounds from a straight-chain hydrocarbon was thought to take place in two steps: first, the rearrangement of n-octane into a branched-chain hydrocarbon:



$$CH_3CH_2CH_2CH_2CH_2CH_2CH_2CH_3 \longrightarrow CH_3\underset{CH_3}{CH}-\underset{CH_3}{CH}-\underset{CH_3}{CH}CH_3$$

and, second, the reaction of the branched-chain hydrocarbon with sulphur to yield the cyclic compound:



The thiophene derivative, $C_8H_{12}S$, in many respects resembled the diethylthiophene described by Muhlert;[47] and the reactions of the thiophthene derivative, $C_8H_8S_2$, indicated it to be the dimethylthiophthene.

On heating higher molecular weight paraffins with sulphur, hydrogen sulphide and carbon disulphide are the principal gaseous products. No identification of any intermediate products appears yet to have been made. Thus, Siebeneck[48] found on heating paraffin wax with sulphur that hydrogen sulphide evolution began at 150° C., and at 230° C. both this substance and carbon disulphide were being evolved. After 7 hours heating the final product obtained was a substance corresponding to the formula $(C_5S)_x$, which was insoluble in organic solvents.

The reaction of paraffins with sulphur to yield hydrogen sulphide has been suggested as a means of preparing this compound. For example, Prothière[49] obtained 48.2 liters of hydrogen sulphide from 70 grams of sulphur and 30 grams of petrolatum. Gfeller and Schaeffer[50] recommended using a mixture of 25 grams of paraffins, 15 grams of sulphur and 5 grams of asbestos fiber. For preparing small quantities of hydrogen sulphide 0.5 to 2.0 cc. of the mixture are heated in a test tube. The evolution of the gas ceases when the source of heat is withdrawn. These investigators represented the reaction by the equation:

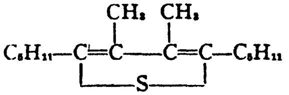
$$C_nH_{2n+2} + S_{n+1} \longrightarrow (n+1)\,H_2S + C_n$$

Bindschedler and Rugeley[51] produced hydrogen sulphide by heating a mixture of hydrocarbon oil and sulphur and purified the gas by passing it through charcoal or some other absorption agent. Scudder and Lyons[51a] investigated the effect of cadmium sulphide, iron, aluminum, zinc, copper, cobalt, lampblack, charcoal, anhydrous aluminum chloride and many other substances on the temperature of initial reaction of sulphur and paraffin. Lampblack and anhydrous aluminum chloride proved to be the best catalysts.

REACTION OF SULPHUR WITH UNSATURATED HYDROCARBONS

In studying the reactions between olefins and sulphur heated under pressure, Friedmann[52] obtained from hexylene and sulphur the following compounds: $C_6H_{12}S$, boiling point 40-41° C. at 10 mm.; $C_{12}H_{14}S$, boiling point 112-113° C. at 10 mm.; and $C_{18}H_{30}S$, boiling point 128° C. at 10 mm. The residue left after the distillation of the reaction products was an asphaltic material whose composition corresponded to the formula $C_{24}H_{20}S_2$. No definite compounds were obtained when n-octylene was heated with sulphur. With methyl-n-amylethylene and sulphur, the thiophene and thiophthene derivatives, $C_8H_{12}S$ and $C_8H_8S_2$ respectively, obtained were the same as those from n-octane, and in addition the two compounds $C_{16}H_{28}S$, and $C_{24}H_{38}S_2$ were formed. The chemical properties of the former indicated that it possessed the structural formula corresponding to



The other compound may have been formed by the condensation of 1 molecule each of $C_8H_{12}S$ and $C_{16}H_{28}S$.

Unsaturated hydrocarbons, containing eight or more carbon atoms, produced by the action of ammonia or other alkalies on di- and poly-chlorinated hydrocarbons, yield various sulphur derivatives when treated with sulphur (or sulphur compounds) by heating under pressure. Oxidation of such derivatives by nitric acid, hydrogen peroxide, or potassium permanganate leads to the formation of sulphonic acids, which have possible uses in the textile industry and in medicine.[53]

REACTION OF SULPHUR WITH CYCLIC HYDROCARBONS

When naphthenes are heated with sulphur, dehydrogenation takes place, accompanied by the evolution of hydrogen sulphide. Markownikow and Spady[54] reported that on boiling octanaphthene, obtained from Caucasian petroleum, with sulphur a small quantity of metaxylene was formed. This was identified by converting it to the trinitro compound, and to mono- and di-sulphonic acids. Markownikow and Spady therefore considered the octanaphthene occurring in this fraction to be hexahydroxylene.

[53] I. G. Farbenindustrie A.-G., British Patents 360,993, 361,356 and 361,357, 1930; *Brit. Chem. Abs.* **B**, 1932, 93.

[54] *Ber.*, 1887, **20**, 1850.

Friedmann,[55] however, suggested that the reaction between sulphur and naphthenes takes place in steps, and that complete dehydrogenation of the hydroaromatic compound to the aromatic does not occur. In fact, dehydrogenation ceases, he believed, with the formation of the dihydride. For example, after heating cyclohexane and sulphur under pressure and fractionating the reaction products under reduced pressure, the lowest boiling fraction on nitration yielded m-dinitrobenzene; from the intermediate fraction boiling between 40° and 60° C. thiophenol was isolated; and in the residue phenyl sulphide was detected. Since benzene was not found among the reaction products Friedmann concluded that dihydrobenzene was present in the lowest boiling fraction, as it would be both oxidized and nitrated by nitric acid to yield m-dinitrobenzene.

The successive steps in the degradation of cyclohexane, according to Friedmann, may be represented by the following equations:

$$C_6H_{12} + S \longrightarrow C_6H_{11}SH$$

$$C_6H_{11}SH \longrightarrow H_2S + C_6H_{10}\ (\textit{cyclohexene})$$

$$C_6H_{10} + S \longrightarrow C_6H_9SH$$

$$C_6H_9SH \longrightarrow H_2S + C_6H_8\ (\textit{cyclohexadiene})$$

The thiophenol may be formed by the reaction of cyclohexadiene with hydrogen sulphide and sulphur:

$$C_6H_8 + 2S + 2H_2S \longrightarrow C_6H_{12}S_4$$

$$C_6H_{12}S_4 \longrightarrow 3H_2S + C_6H_5SH$$

Friedmann also observed that on heating methylcyclohexane with sulphur and fractionating the reaction products, the portion boiling between 100.5° and 120° C. yielded trinitrotoluene on nitration. Thiocresol was isolated from the fraction boiling between 80° and 130° at 11 mm.

The different fractions obtained from the reaction product of 1,3-dimethylcyclohexane and sulphur reacted more or less strongly with bromine or permanganate, indicating the presence of unsaturated compounds. The fraction boiling between 30° and 90° C. at 11 mm. yielded trinitro-m-xylene on nitration, and thio-m-xylene was found in the fraction boiling between 90° and 110° C. at 11 mm., and m,m′-dimethyldibenzyl, in the fraction boiling between 110° and 180° C. at 11 mm. This latter hydrocarbon could be obtained by heating m-xylene and sulphur under pressure.

PRODUCTION OF SULPHUR DYES

Sulphur dyes were made by Palmer and Lloyd[56] by passing either gaseous hydrocarbons or the vapors of higher-boiling hydrocarbons through molten sulphur at 350° to 400° C. For example, acetylene, ethylene, and kerosene yield dyes which are bluish-black solids, and which contain about 68, 61, and 62 per cent, respectively, of sulphur. These dyes are true sulphur dyes as they are soluble in sodium sulphide solution and can be applied directly to cotton, rayon, and other fibers. The dyes are fast to repeated washing with soap and water, and to organic solvents. When applied to cotton or rayon the dye obtained from ethylene imparts a reddish-brown color to the fiber, that from acetylene, a gray color, and that from kerosene, a khaki color.

[56] *J.A.C.S.*, 1930, 52, 3388.

Numerous other organic substances react with sulphur in a similar manner, for example, aromatic hydrocarbons (such as benzene, toluene and diphenyl), amines (such as aniline or diethylaniline), aldehydes, ethers, acids and alcohols. All of the dyes so produced possess a high sulphur content, usually about 60 to 80 per cent, except that from ethyl alcohol which contains only about 10 per cent sulphur.

MERCAPTANS

In the petroleum industry more work has probably been done with mercaptans and a better knowledge of their chemistry obtained than with any other class of sulphur compounds. The reasons for this are apparent since, as a class, the mercaptans react readily and their reactions with various reagents are therefore not as difficult to follow as those of other sulphur compounds: furthermore, the total quantity of such compounds present in the distillates from various high-sulphur crude petroleum oils is relatively large. In fact, it has been estimated that if all of the mercaptans present in unrefined naphthas in this country alone could be recovered there would be available from 150 to 200 tons per day.[57] In spite of the knowledge of the chemistry of these compounds and the quantity available, few processes have been developed for their removal from petroleum distillates and their utilization. Practically all of the proposed operations consist of the sweetening of distillates, or the conversion of mercaptans to disulphides.

While it is unnecessary here to enter into a detailed discussion of the synthesis and chemical proporties of the mercaptans, some of their typical reactions will be mentioned.

The most general reaction employed in the synthesis of aliphatic mercaptans is that between potassium or sodium hydrosulphide and alkyl halides. The reaction of alcohols and phosphorus pentasulphide to yield mercaptans is applicable to both aromatic and aliphatic compounds, and with this same reagent phenols yield mercaptans or thiophenols, with the sulphur attached directly to the benzene nucleus. Distillation of a mixture of the alkali salts of sulphuric acid esters with alkali hydrosulphides also yields this same class of compounds. These methods of preparation may be represented by the following typical reactions:

$$\text{(a)}\quad C_2H_5Cl + KSH \longrightarrow C_2H_5SH + KCl$$

$$\text{(b)}\quad 5C_2H_5OH + P_2S_5 \longrightarrow 5C_2H_5SH + P_2O_5$$

$$\text{(c)}\quad 5C_6H_5OH + P_2S_5 \longrightarrow 5C_6H_5SH + P_2O_5$$

$$\text{(d)}\quad C_2H_5SO_4Na + NaHS \longrightarrow C_2H_5SH + Na_2SO_4$$

An interesting method for the preparation of tertiary mercaptans, particularly *ter*-butyl mercaptan, is by the interaction of sulphur and magnesium *ter*-butyl chloride in ether solution.[58] This mercaptan could not be separated from its ether solution by distillation. It was therefore precipitated as its mercury salt, and the latter decomposed with liquid hydrogen sulphide to yield mercuric sulphide and the free mercaptan.

With the exception of methyl mercaptan which is normally a gas, the aliphatic mercaptans are generally liquids possessing boiling points somewhat lower than the corresponding alcohols.[59] This difference of boiling point, however, becomes less as the number of carbon atoms in the molecule increases. For example, the boiling points of ethyl mercaptan and ethyl alcohol have been reported as 34.7° to 37° C. and 78.4° C., respectively, while the boiling points of n-heptyl mercaptan and the corresponding alcohol have been given as 174° to 175° C. and 175.8° C., respectively. In the aromatic series greater irregularities are encountered with respect to both boiling points and melting points, due no doubt to the effect of substituent groups. The specific gravities of aliphatic mercaptans are generally less than 1, ranging from about 0.83 to 0.89, while the aromatic mercaptans are usually heavier than water. The mercaptans of lower molecular weight possess disagreeable and unpleasant odors, while those of high molecular weight, such as myricyl mercaptan ($C_{30}H_{61}SH$), are odorless. Some aromatic mercaptans of fairly low molecular weight, such as o-xylene dimercaptan, have been described as odorless. Incidentally, because of its penetrating odor, volatility, and insolubility in water, ethyl mercaptan in concentrations of 4 grams per 1000 cubic feet of gas has been used for the detection of leaks in gas mains.[60]

---

[58] Rheinboldt, Mott and Motzkus, *J. pr. Chem.*, 1932, (3) 134, 257; *Chem. Abs.*, 1932, 26, 5544.

As the mercaptans contain an —SH group they may be considered as derivatives of hydrogen sulphide, or as alcohols in which the oxygen atom has been replaced by sulphur. As derivatives of hydrogen sulphide the mercaptans should be acidic in nature and some of their reactions bear this out. Just how acid the individual mercaptans are, and how they stand in relation to one another, apparently has not been determined on the basis of conductivity methods.[61] With alkalies, such as sodium or potassium hydroxides, or with metallic hydroxides, or oxides, the corresponding salts, or mercaptides, are formed. As these reactions are of particular interest in the sweetening operation they are more fully discussed later.

One of the characteristic reactions of mercaptans is that with oxidizing agents. With mild oxidizing agents, such as iodine, particularly under alkaline conditions, the mercaptans are converted to disulphides.[61a] This reaction has served for a quantitative estimation of mercaptans.[62] Reid and Sampey [63] have described two acidimetric methods for the determination of mercaptans (in benzene solutions). In the first method the hydrogen iodide formed in the oxidation of mercaptans with iodine is titrated; while in the second, the hydrogen chloride liberated by the action of mercuric chloride on the mercaptans is estimated. The latter reaction is given as:

$$RSH + HgCl_2 \longrightarrow RSHgCl + HCl$$

With chlorine or bromine, the mercaptans also yield disulphides, though side reactions take place at the same time with the formation of other products, such as sulphobromides, sulphones, and sulphonic acids. These reactions with halogens may be represented by:

---

[62] For the determination of mercaptans with iodine in acid solution, see Kimball, Kramer and Reid, *J.A.C.S.*, 1921, **43**, 1199.

[63] *J.A.C.S.*, 1932, **54**, 3404.

$$2C_2H_5SH + I_2 \longrightarrow 2HI + C_2H_5S.SC_2H_5$$
$$2C_2H_5SH + Br_2 \longrightarrow C_2H_5S.SC_2H_5 + 2HBr$$
$$2C_2H_5SH + 3Br_2 \longrightarrow 2C_2H_5Br + 2HBr + 2BrS$$
$$C_6H_5SH + Cl_2 \longrightarrow C_6H_5SCl + HCl$$

Other oxidizing agents which react with mercaptans to form disulphides are atmospheric oxygen, ferric chloride, ferricyanides, and sulphur. More energetic oxidizing agents, for example nitric acid, convert mercaptans into sulphonic acids.

$$2RSH + S \longrightarrow H_2S + RS.SR$$
$$2RSH + 2FeCl_3 \longrightarrow 2FeCl_2 + 2HCl + RS.SR$$
$$RSH + 2HNO_3 \longrightarrow RSO_3H + H_2O + 2NO$$

In carbon bisulphide solutions mercaptans react with sulphur monochloride to yield polysulphides,[64] for example:

$$2RSH + S_2Cl_2 \longrightarrow (RS)_2S_2 + 2HCl$$

Reaction with thionyl chloride leads to a mixture of disulphide and trisulphide,[65] thus:

$$4RSH + SOCl_2 \longrightarrow R_2S_2 + R_2S_3 + H_2O + 2HCl$$

The relation of mercaptans to alcohols is shown by the fact that mercaptans esterify organic acids just as alcohols do. The limits of esterification appear to be lower, however, with the mercaptans than with the corresponding alcohols.[66] The general reaction may be represented by

$$RCOOH + HSR \longrightarrow H_2O + RCOSR$$

The reactions of mercaptans with aldehydes[66a] to form mercaptals and with ketones to form mercaptoles appear to be characteristic.[66b] Some of the sulphones of the latter compounds have found use as soporifics; as for example sulphonal $(CH_3)_2C(SO_2C_2H_5)_2$, which is the sulphone of the mercaptole obtained by the reaction of acetone with ethyl mercaptan.[67] In this connection it may be mentioned also that carbohydrates similarly form condensation products with mercaptans; and that optically active amyl mercaptan, prepared from the corresponding alcohol, has been used in the resolution of racemic saccharides.[68]

One interesting point concerning the optical activity of some mercaptans is the reversal of rotation on oxidation. Thus Levene and Mikeska[69] have observed that oxidizing 2-mercaptoisohexane, $[\alpha]^{20}_{D} = +21.21°$, with nitric acid produced 2-isohexanesulphonic acid having $[\alpha]^{20}_{D} = -6.7°$. Also, 1,2-diphenylethyl mercaptan, $[\alpha]^{20}_{D} = +8.56°$, on oxidation yielded 1,2-diphenylethylsulphonic acid having $[\alpha]^{20}_{D} = -36.40°$. This reversal of rotation is similar to that observed by these same workers with other mercaptans[70] on oxidation and also resembles that accompanying the halogenation of secondary alcohols.[71]

In addition to the uses already pointed out the bathochromic action of mercaptan groups in azo dyes might be mentioned, as the introduction of such a group often deepens the shade of the color.[72] Other types of dyes for which various mercaptans serve as intermediates are those of the anthraquinone series, thioindigos, and indamines. In addition the metallic salts of certain amino mercapto compounds, of mercapto acid esters, and of thioglucose have found some application in therapeutics. The synthesis of various mercapto compounds also appears to be of interest in the rubber field.[73]

The use of mercaptans as pickling inhibitors has been proposed by Calcott and Lee.[74] One of the chief disadvantages connected with the acid treatment of metals is that the free metal is attacked. Some substances which have been suggested as inhibitors of this solvent effect of the acid on the metal are sulphonated slaughterhouse waste and sludges from the sulphuric acid treatment of coal-tar and petroleum products. Both alkyl and aryl mercaptans possess this inhibiting effect to a marked degree, though their value varies with the kind and concentration of acid used, the temperature of the bath and the type of metal. The inhibiting action of some of the more common mercaptans on mild steel treated at 60° C. with 5 per cent sulphuric acid, containing 0.3 per cent mercaptan, was as follows:

	Inhibition Per Cent
Thiophenol	96.1
Thio-betanaphthol	93.1
Benzyl mercaptan	99.93
Isoamyl mercaptan	99.93
Isopropyl mercaptan	99.84

The inhibitor may be mixed with an acid dispersing agent such as Twitchell's reagent, Turkey red oil or sludge acids, or it may be dispersed in concentrated acids. If the inhibitor should decrease the rate of reaction to such an extent that the time for pickling is unduly prolonged, its action can be offset by the addition of a metallic chloride such as sodium chloride.

Derby and Cunningham[75] have reported that either aliphatic or aromatic mercaptans when heated to about 115° to 125° C. with phosphorus pentasulphide, or trisulphide, yield a product which is a clear syrupy liquid, and which, because of its collecting power, can be used in ore-flotation processes. Similar products can be obtained from the alkali ethoxides or phenoxides and phosphorus pentasulphide.

With the advent in the petroleum refinery of methods for the isolation of mixtures of the lower aliphatic mercaptans (methyl, ethyl, propyl or isopropyl) many other interesting applications will no doubt be found for compounds of this type.

Some of the reactions of mercaptans which have been described will be discussed in more detail, particularly those used in the extraction of such sulphur compounds from petroleum.

Reaction of Mercaptans with Alkalies

In the refining of petroleum distillates, particularly from high sulphur crude oils, it is customary to wash them with solutions of sodium hydroxide before treating with sulphuric acid or before sweetening by the use of sodium plumbite solution. This alkali wash is given in order to eliminate the hydrogen sulphide dissolved in the distillate, as this substance is oxidized by the sulphuric acid with a corresponding loss of acid; or it reacts with the lead present in the plumbite solution to form lead sulphide, thereby resulting in an excessive consumption of lead.

Some mercaptans are extracted from the distillate by this alkaline wash as alkali salts or mercaptides. Complete extraction of mercaptans cannot be secured in this manner, except possibly of low-boiling ones, or when only a small proportion are present. This is due to the fact that alkali mercaptides, like the alkali sulphides, are readily hydrolyzed. The reaction therefore between alkali, in aqueous solution, and mercaptans can be represented by the reversible equation

$$\mathrm{RSH} + \mathrm{NaOH} \rightleftharpoons \mathrm{RSNa} + \mathrm{H_2O}$$

Alkaline extraction as a means of purification of naphtha likewise provides a method for the concentration of the lower mercaptans as their alkali mercaptides. From this alkaline extract the mercaptans themselves can be recovered by blowing with steam, yielding a mixture of ethyl and methyl mercaptan, sometimes with propyl or isopropyl mercaptan. In this way an alkaline washing liquor may be largely freed from sulphur. By blowing the liquor with air instead of steam, disulphides are formed.

Solutions of the lower-boiling mercaptans may be obtained in the following manner. Sour petroleum distillates, such as gasoline or kerosene, are treated with a 20 per cent aqueous solution of sodium hydroxide until the free alkali content of the solution has decreased to 10 per cent or less. This yields a solution containing both sodium mercaptides and sodium sulphide. Treatment of this solution with calcium hydroxide converts the sodium sulphide to sodium hydroxide and calcium sulphide is precipitated, which may then be separated. Spent lime solutions, composed largely of calcium hydrosulphide, may be used in place of calcium hydroxide.[76]

By extracting distillates containing mercaptans with sodium hydroxide solutions of different concentrations and then determining the distribution ratios, Meyer[77] obtained results which indicated that for the same weight of sodium hydroxide the more dilute solutions extracted the larger proportion of mercaptans. For the same strength of caustic soda solution, however, the quantity of mercaptans extracted was not proportional to the volume of solution used; thus, doubling the volume of caustic solution used did not double the quantity of mercaptans extracted. A countercurrent extraction using a series of pumps and settling tanks and enough caustic soda solution to remove the mercaptans gave better results than did batch treating. The efficiency of such a system was represented by $\frac{n}{n+1}$, in which n is the number of stages. The efficiency of a four-stage system, for example, would be 80 per cent. The mercaptans could be recovered by boiling the caustic solution.

Countercurrent extraction by caustic soda solution containing dissolved lead compounds, or by aqueous solutions of salts such as copper or magnesium chlorides, has been described by Peterkin.[78] Such solutions may be regenerated by blowing with a stream of air, or other oxygen-containing gas mixtures.

---

[76] Wendt, U. S. Patent 1,791,179, Feb. 3, 1931; assigned to Standard Oil Company of Indiana; *Chem. Abs.*, 1931, **25**, 1667.

[77] *J. Inst. Pet. Tech.*, 1931, **17**, 621.

Vesselovsky and Kalichevsky[79] have reported that mercaptans can be extracted quantitatively from naphtha by sodium or potassium hydroxide dissolved in absolute alcohol. The reaction appears to be the formation of mercaptides and water, and the hydrolysis of the mercaptides in alcohol is extremely low.

When dissolved in petroleum distillates mercaptans not only react with aqueous and non-aqueous solutions of alkalies, but also with solid alkalies. Vesselovsky and Kalichevsky[80] observed that both solid sodium and potassium hydroxides extract mercaptans, sodium hydroxide reacting more rapidly than potassium hydroxide.

When mercaptans are added to liquid ammonia, slightly soluble ammonium mercaptides are formed.[81] These substances are white, crystalline bodies. On the addition of metallic sodium to a solution of these mercaptides in liquid ammonia a rapid reaction takes place with the formation of sodium mercaptide, ammonia and hydrogen.

$$RSH + NH_3 \longrightarrow RSNH_4$$
$$2RSNH_4 + 2Na \longrightarrow 2RSNa + 2NH_3 + H_2$$

Billheimer and Reid[82] observed that when the alkaline solutions of mercaptans are heated to temperatures of about 260° C., three simultaneous reactions take place: the formation of (1) alcohol, (2) thioethers, and (3) olefins. These may be represented by the following equations:

$$(1)\quad RSH + 2NaOH = ROH + Na_2S + H_2O$$
$$(2)\quad 2RSH + 2NaOH = R_2S + Na_2S + 2H_2O$$
$$(3)\quad RCH_2CH_2SH + 2NaOH = RCH{=}CH_2 + Na_2S + H_2O$$

Secondary mercaptans react to a greater degree than the primary; for example, when heated for 2 hours at 260° C. with $3N$ caustic solution 52.2 per cent of n-propyl mercaptan reacted with the alkali, while under the same conditions 65.4 per cent of isopropyl mercaptan reacted.

These reactions are also affected by the temperature as shown by the following results obtained with n-butyl mercaptan and $3N$ caustic solution on heating for 2 hours:

Temperature	250° C.	260° C.	270° C.
Per cent mercaptan reacting	30	49.6	63

When heated for 4 hours at 250° C. it was found that 47.2 per cent of the mercaptan reacted, thus indicating the favorable influence of time on the reaction.

The strength of the alkali also plays a very important part. As shown in Table 91, which gives the percentage decomposition of n-butyl mercaptan when heated for a period of 2 hours at 260° C. with sodium hydroxide solutions of various concentrations, the percentage of the mercaptan decomposed is greater with the more concentrated solutions, varying almost directly as the concentration. One curious fact noted by Billheimer and Reid is that thioethers constituted a much higher percentage of the decomposition products when dilute alkali was used than with the more concentrated solutions.

Per cent decomposed	0.0	2.1	9.8	20.2	33.8	49.6
R_2S formed	0.0	1.7	4.9	5.4	7.8	8.1
Per cent R_2S	—	81	50	27	28	16

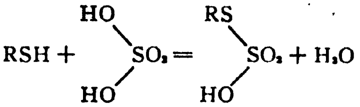
This "desulphydration" of mercaptans has been observed also with aralkyl mercaptans.[83] When α-phenylethyl-, β-phenylethyl-, or γ-phenylpropyl-thiols were heated to 230° C. with solid potassium hydroxide hydrogen sulphide was eliminated and the corresponding olefin obtained. A 53 per cent yield of the olefin was obtained from the β-phenylethylthiol, while very much lower yields were given by the other two thiols.

The sweetening of light sour distillates by countercurrent extraction with hot alkaline solutions has been proposed by Kimball.[84] In his process the aqueous alkaline solution is kept at a temperature which is high enough to maintain the distillate in the vapor phase. Evaporation of the alkaline solution may be prevented by the application of pressure. It is probable that the reactions taking place during this procedure are, at least in part, those described above.

ACTION OF SULPHURIC ACID ON MERCAPTANS

As sulphuric acid is almost universally employed in the refining of petroleum distillates its action upon mercaptans is of interest.

Erlenmeyer[85] was probably the first to show that mercaptans could be oxidized to the corresponding disulphides by the use of concentrated sulphuric acid. Wood, Lowy and Faragher[86] showed that by treating naphtha solutions of n- and iso-amyl mercaptans with concentrated sulphuric acid the mercaptans are oxidized to disulphides. They further reported that after treating these solutions of mercaptans with a relatively small quantity of sulphuric acid, the sulphur content increased. This increase in sulphur content was not observed on treating the naphtha alone with sulphuric acid. When the naphtha solutions were treated with large proportions of acid a decrease in sulphur content occurred, indicating that the disulphides were dissolved by the acid. Lowy and his collaborators suggest, therefore, that this increase in sulphur content may have been due to the formation of intermediate oxidation products, alkyl acid thiosulphates or dithiosulphates (equations 1 and 2 below), when the quantity of acid used was not sufficient for completely oxidizing the mercaptan to disulphide.



$$RSH + (HO)_2SO_2 = (RS)(HO)SO_2 + H_2O \qquad (1)$$

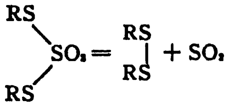
(2)



(3)

Bennet and Story[87] concluded, from their study of the action of sulphuric acid on butyl mercaptan dissolved in gasoline, that not only was butyl disulphide and the corresponding sulphone ($C_4H_9S \cdot SO_2C_4H_9$) formed but also some elemental sulphur due to a side-reaction.

During the refining of certain light petroleum distillates with sulphuric acid Birch and Norris[88] observed that a small quantity of a substance was formed which was soluble in the distillate, insoluble in sulphuric acid, and corrosive to copper at the boiling point of the naphtha. The formation of this particular type of substance took place only when mercaptans were present in the untreated distillate. An investigation of various organic sulphides led to the conclusion that trisulphides were the cause of this corrosion. Diethyl trisulphide, $C_2H_5SSSC_2H_5$, synthesized from ethyl mercaptan and sulphur dichloride possessed the characteristic properties of the corrosive substance. Similar trisulphides were obtained by dissolving isobutyl or isoamyl mercaptans in naphtha and agitating with rock sulphur. Birch and Norris therefore consider that the formation of a polysulphide takes place, when sour crude distillates (i.e., distillates containing mercaptans) are treated with sulphuric acid, the reaction being represented by the equation:

$$2RSH + 2S \longrightarrow H_2S + R_2S_3$$

SWEETENING REACTION

By sweetening is generally meant the oxidation of mercaptans which are present in petroleum distillates, particularly gasoline and kerosene, to disulphides. One object of this process is improvement of odor, as the mercaptans, or at least those occurring in the petroleum distillates, possess very disagreeable odors, while the disulphides do not possess as unpleasant an odor and their presence in the distillates is not objectionable on this ground. Because, as previously mentioned, mercaptans are corrosive compounds and also catalysts for gum-formation, sweetening is almost imperative as a corrective measure in the manufacture of gasoline and kerosene. Any process which involves the actual removal or extraction of mercaptans, instead of their oxidation to disulphides, would, of course, yield a sweet oil.

Sweetening is usually accomplished by agitating the sour distillate with lead oxide dissolved in sodium hydroxide solution and then adding sulphur to precipitate the lead. Various modifications of this method are possible: for example, mixing a sufficient volume of oil containing dissolved sulphur with the sour oil and then agitating the mixture with the doctor solution; or agitating the sour distillate with the doctor solution, separating the aqueous layer, and adding

[87] *Oil and Gas J.*, 1927, 27 (48), 162; *Chem. Abs.*, 1927, 21, 2979.
[88] *Ind. Eng. Chem.*, 1929, 21, 1087.

a sufficient volume of oil containing dissolved sulphur to precipitate the lead.[89] Addition of solid sulphur to the sour oil after agitating with the doctor solution is also practiced.

The usual explanation [89a] of the reactions which take place during sweetening are: (1) reaction of the sour oil with the plumbite or doctor solution to form lead mercaptides which dissolve in the oil, imparting to it a yellow color; and (2) the subsequent formation of lead sulphide and disulphides on the addition of sulphur. The lead sulphide is insoluble in the oil and after precipitating is removed. The equations for these reactions are:

$$2RSH + Na_2PbO_2 = 2NaOH + Pb(SR)_2$$
$$Pb(SR)_2 + S = PbS + (RS)_2$$

This same procedure, agitation of the oil with doctor solution followed by the addition of sulphur, is the basis for the well-known doctor test.[89b] The formation of a precipitate on the addition of sulphur indicates a sour oil, while failure to form any precipitate indicates a sweet oil. It is customary before applying the doctor test to remove any hydrogen sulphide which may be present. This is necessary as hydrogen sulphide reacts immediately with the doctor solution to yield a precipitate of lead sulphide, and therefore interferes with the doctor test. Samples of sweet gasolines which have been stored for some time occasionally test sour, because of the formation of peroxides which react with the doctor solution to yield the insoluble lead peroxide.[90] Even turpentine, which contains no sulphur compounds, after exposure to air has shown a positive doctor test, because of the peroxides present. In applying the doctor test to stored samples, peroxides should therefore be eliminated by washing with solutions of alkalies (see Chapter 39) or by some other means.

While the reactions first mentioned are known to occur, there are other chemical changes which take place and the sweetening process is therefore much more complicated than these indicate. Wendt and Diggs [91] have shown that not only are mercaptans converted to disulphides by the oxidizing action of sulphur on their lead salts, but that the lead sulphide formed during sweetening is itself an active sweetening agent because of its property of absorbing mercaptans, thereby promoting their reaction with the doctor solution. Other sulphur compounds are absorbed at the same time. Wendt and Diggs have also pointed out that some distillates, such as pressure distillates, contain enough free or elemental sulphur to react with the lead mercaptides formed during the sweetening operation, and the addition of sulphur to such an oil is unnecessary.

Morrell and Faragher,[92] however, did not agree with this explanation of the use of lead sulphide. Instead they suggested that the lead sulphide is oxidized to lead sulphate by the air used for agitation, and that this lead sulphate then reacts with the sodium hydroxide to form sodium plumbite. From there on the usual sweetening reaction occurs. This they considered was indicated by the fact that a sample of sour commercial gasoline still gave a positive doctor test

[89] Chatfield, *Nat. Pet. News,* July 18, 1928, 56. Sturgis (*Oil and Gas J.,* 1933, 31 (45), 54; *Chem. Abs.,* 1933, 27, 3593) reports that gaseous hydrogen sulphide may be employed in place of elemental sulphur to precipitate the lead.

[89a] For a résumé of the theoretical principles involved as well as descriptions of batch and continuous processes of plumbite treatment, see Hallett and Sowers, *Petroleum Eng.,* 1930, 1 (8), 78; *Chem. Abs.,* 1930, 24, 3892.

[89b] For a comparison of the doctor and silver nitrate tests for mercaptans in gasolines see Mizuta, *J. Soc. Chem. Ind. Japan,* 1931, 34, 287; *Chem. Abs.,* 1931, 25, 5976. The estimation of mercaptans by the silver nitrate method is described by Borgstrom and Reid, *Ind. Eng. Chem., Anal. Ed.,* 1929, 1, 186; see also Chapter 50.

[90] Brooks, *Ind. Eng. Chem.,* 1924, 16, 588.

[91] *Ind. Eng. Chem.,* 1924, 16, 1113.

[92] *Ind. Eng. Chem.,* 1927, 19, 1045.

after 30 minutes agitation with air alone or in the presence of (1) sodium hydroxide, or (2) sodium hydroxide and lead sulphide. In the presence of lead sulphide, sulphur and sodium hydroxide (that is, all the ingredients required for sweetening) the sample was sweetened in 8 minutes and the alkaline solution then gave tests for a large proportion of sulphate ion. The reactions taking place can be represented in the following manner:

$$\begin{aligned} &PbS + 2O_2 \longrightarrow PbSO_4 \\ &PbSO_4 + 4NaOH \longrightarrow Na_2PbO_2 + Na_2SO_4 + 2H_2O \\ &2RSH + Na_2PbO_2 \longrightarrow 2NaOH + Pb(SR)_2 \\ &Pb(SR)_2 + S \longrightarrow PbS + (RS)_2 \end{aligned}$$

Other sulphides, such as those of silver, copper, mercury, and nickel, can be used instead of lead sulphide. When air is blown into suspensions of these sulphides in caustic soda solution, all are converted to the corresponding hydroxides, except mercury, which forms the oxide.

Lead sulphide as a sweetening reagent has been employed[93] with distillates in which the mercaptan content is so high that doctor sweetening becomes practically prohibitive on account of expense. The oil is agitated with caustic soda solution, sulphur, and a relatively small quantity of lead sulphide by blowing air through the mixture. In this way the mercaptans are said to be converted into less volatile polysulphides which remain in the still on subsequent redistillation. The temperature during redistillation should not exceed 160° C., to prevent decomposition of the polysulphides. Other heavy metallic sulphides can be used in place of lead sulphide.

Lachman,[94] on the other hand, believed that the interpretations given by Wendt and Diggs and by Morrell and Faragher are correct, because of the fact that both of the side reactions take place simultaneously. Confusion has arisen because gasolines are tested only to learn whether they are sweet or sour, and not quantitatively to determine how much mercaptan remains after each operation.

In studying the action of air on mercaptans in the presence of sodium hydroxide, Lachman used a 315 cc. flask in which were placed definite volumes of sodium hydroxide solutions of various concentrations and of sour gasoline. This left a definite volume of air remaining in the flask, which contained sufficient oxygen for the complete oxidation of the mercaptans. The flask and its contents were agitated at 20° to 25° C. for a definite period of time and the mercaptan content of the gasoline was determined. Some of the results obtained are given in Table 92.

These, and other results, clearly indicate that oxidation of mercaptans by air occurs in the presence of alkaline solutions. In some instances the mercaptans

[94] *Ind. Eng. Chem.*, 1931, **23**, 354.

were completely oxidized. The reactions taking place may be represented, according to Lachman, by the equations:

$$2RSH + O_2 = RSSR + H_2O_2$$
$$2RSH + H_2O_2 = RSSR + H_2O$$

The second reaction takes place very rapidly, and would be completed almost as soon as the primary reaction.

Lachman's data further indicated that the mercaptide ion, not the mercaptan, is actually oxidized, and that the rate of oxidation is governed by, the speed of diffusion of atmospheric oxygen into the alkaline layer. If the rate of oxidation is determined by the alkaline film and its oxygen content then this rate would be increased by increasing (1) the air pressure, (2) the area of the film by agitation, and (3) the surface of contact by the addition of finely divided solids. The second inference was verified by using very small quantities (1 cc.) of sodium hydroxide solution and agitating with sour gasoline in the presence of air as described above. The third inference was also verified by the addition of various catalysts, such as lead, cadmium, and zinc sulphides, barium sulphate and others, to the alkaline solution. The effects of such catalysts are shown in Table 93.

TABLE 93.—*Effect of Catalysts on Rate of Oxidation of Mercaptans.*
100 cc. of Gasoline; Mercaptan 0.0118*M*; 25 cc. of
2*M* NaOH + Catalyst; Air Volume 190 cc.

Catalyst	Mol.	Time	Mercaptan Oxidized Per Cent
Cadmium sulphide	0.001	1 hour	sweet
Zinc sulphide	0.001	1 "	87
Lead sulphide	0.0005	15 minutes	99+
Barium sulphate	0.002	20 "	58
Sulphur	0.03	10 "	sweet
None	—	1 hour	43

In other experiments it was found that lead sulphide was changed to lead oxide, and therefore one equivalent of litharge during the course of the reaction would react with more than two equivalents of mercaptans. Further, the presence of any sodium sulphide which might be formed during the sweetening process is detrimental only because in being converted to sodium thiosulphate it competes with the mercaptans for both free oxygen and sulphur.

NEUTRAL AND BASIC LEAD MERCAPTIDES

Ott and Reid[95] have found differences in the reactions between primary and secondary mercaptans with the doctor solution, and also in the subsequent reactions between the lead mercaptides thus formed and elemental sulphur.

When solutions of mercaptans in benzene are agitated with sodium plumbite solution two reactions are possible, (1) formation of neutral lead mercaptide, and (2) formation of basic lead mercaptide.

(1) $Pb(OH)_2 + 2RSH \longrightarrow Pb(SR)_2 + 2H_2O$

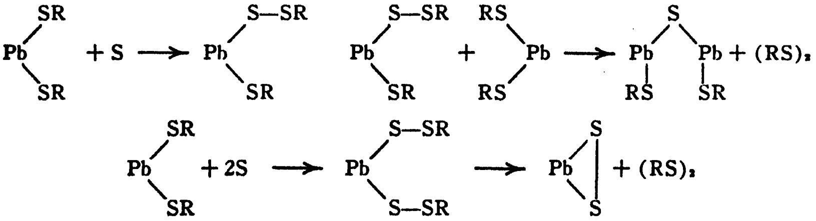
(2) 
$$Pb(OH)_2 + RSH \longrightarrow Pb\begin{matrix} \diagup SR \\ \diagdown OH \end{matrix} + H_2O$$

---

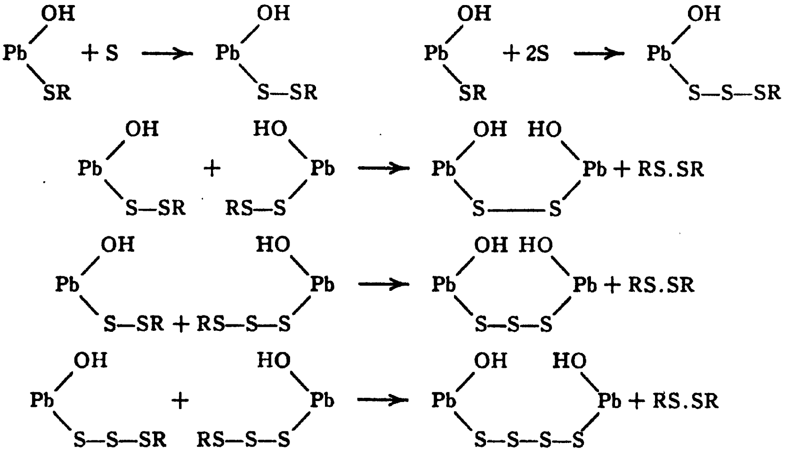
[95] *Ind. Eng. Chem.*, 1930, 22, 878, 884

While both types of mercaptides are formed in all cases, the following generalizations appear to hold: the primary mercaptans form principally neutral lead mercaptides, the secondary mercaptans tend to form large quantities of the basic lead mercaptides, and the more concentrated the sodium plumbite solution the greater is the quantity of basic lead mercaptides in both instances.

The addition of sulphur to solutions of lead mercaptides does not, therefore, always lead to the formation of lead sulphide, as has been generally assumed. The addition of sulphur to solutions of neutral lead mercaptides usually results in the formation of a precipitate consisting of a mixture of lead-sulphide and the neutral lead mercaptide. It was reported that in one instance lead disulphide was formed. Reactions whereby such products could be formed might be represented in the following manner:



The addition of sulphur to solutions of basic lead mercaptides results in formation of precipitates which analysis shows to be mixtures of lead sulphide, lead hydroxide and sulphur.[96] In some instances—from the basic lead mercaptide of *sec*-butyl mercaptan, for example—compounds of the type $Pb_2(OH)_2S_3$ and $Pb_2(OH)_2S_4$ were obtained. The formation of such compounds may take place according to the following reactions:



When solutions of lead mercaptides are exposed to the air fairly stable peroxides of high, though varying, oxygen content are formed, which are insoluble in organic solvents.[97] They are also produced by the action of hydrogen peroxide on solutions of the mercaptides. From the lead mercaptide of *sec*-butyl mercaptan the peroxide, $Pb(SC_4H_9)_2O_8$, was obtained. As all tests failed to indicate that any of the oxygen was attached to the lead it was assumed that the constitution of the compound could be represented by  Peroxides of smaller oxygen content were also obtained from this same lead mercaptide. Light appeared to accelerate the formation of the peroxides.

---

[96] Duncan and Ott (*J.A.C.S.*, 1932, 54, 4463) report that the basic lead derivatives of secondary butyl mercaptan (in benzene) react with sulphur to yield a mixture of basic lead polysulphides. No definite compounds could be isolated.

OTHER METHODS OF SWEETENING

Instead of adding sulphur to the sour oil after agitation with the doctor solution Hunn[98] suggested the addition of low molecular weight disulphides such as methyl or propyl disulphide. On standing, the lead is precipitated and a sweet oil obtained. Analysis of the precipitate formed from methyl disulphide indicated it to be lead methyl mercaptide.

For use in place of a solution of lead oxide Cannon and Gary[99] have suggested employing a solid reagent consisting of calcium hydroxide, lead oxide and sulphur. After mixing this reagent with the sour oil the mixture is filtered and a sweet oil obtained. The solid reagent, after the addition of sulphur, can be used again.

A modification of this process consists in first adding a small quantity of sulphur to the gasoline and then treating it with a mixture consisting of sodium hydroxide, calcium hydroxide, lead oxide, diatomaceous earth, and enough water to form a coherent mass.[100]

Brucite, or magnesium hydroxide, has been used as a sweetening agent. In this case elemental sulphur equivalent to that required for the oxidation of the mercaptans to disulphides is added to the sour distillate, and the distillate is then agitated with solid brucite.[101]

Other methods for sweetening petroleum distillates have been suggested. Lachman[101a] found that gasoline could be made sweet by agitating it with air in the presence of alkaline solutions containing finely divided carbon in suspension. Zurcher[101b] passed hydrocarbon vapors at 400° to 600° C. through activated carbon, the velocity of the vapors being rapid enough to avoid cracking. Malisoff[101c] treated oils containing mercaptans with solutions of an alkali metal hydroxide in methyl alcohol, sufficient water being added to the alcoholic solution to render it immiscible with the oil. Black and McConnell[101d] recommended aqueous solutions of alkalies with suspended manganese dioxide as contact agents. Exposure of sour distillates, after treatment with plumbite solution, to ultraviolet light results in the precipitation of the mercaptides.[101e] The oxidation of mercaptans by air is accelerated by x-rays.[101f] Solid sodium hydroxide has been used to give a negative doctor test to gasolines.[101g] Moser[101h] reported that a sweet but corrosive product was obtained when dry sodium hydroxide, or powdered sodium carbonate, and free sulphur were employed. The use of phosphorus pentoxide as a sweetening agent has also been proposed.[101i]

The use of hypochlorite solutions as sweetening agents in place of the doctor solution and sulphur has also been proposed. Thus Dunstan[102] sweetened a sour distillate by first removing hydrogen sulphide and then treating with a dilute solution of hypochlorous acid. Later the product is refluxed with slacked lime to hydrolyze any chlorinated compounds which might have been formed. Birch and Norris,[103] however, used an alkaline hypochlorite solution for the sweetening operation with cracked distillates. With this reagent hydrogen sulphide is oxidized to elemental sulphur and a small proportion of sulphuric acid, sulphides are oxidized to neutral sulphones, and mercaptans first to disulphides and then to sulphonic acids. As the oxidizing effect of the hypochlorite solution decreases with increasing alkalinity it is possible to adjust the alkalinity so that mercaptans are oxidized only to disulphides. Oxidation of mercaptans is also effected by chlorous acid in the presence of hydrochloric acid.[103a]

Demoulins and Garner[104] suggested the vapor-phase sweetening of petroleum distillates by treating the vapors with atomized hypochlorite solution.

COPPER MERCAPTIDES

Although the sweetening of sour oils is accomplished usually by the use of the sodium plumbite and sulphur, or some modification such as lead sulphide, caustic and air, or by the use of hypochlorite solutions, the employment of copper[105] salts has also been suggested. To effect this reaction, the sour oil is agitated with a water solution of a cupric salt, usually cupric sulphate, to which enough ammonia has been added to form the blue solution of ammonio-cupric sulphate. Light yellow cupric mercaptides are formed which are soluble in the oil. Addition of sulphur then precipitates cupric sulphide, yielding a sweet oil.[105a] Von Fuchs[105b] suggested agitation of the sour distillate with finely divided copper or cuprous oxide in the presence of a trace of ammonia, hydrogen chloride or sulphur dioxide.

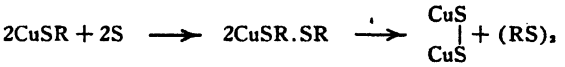
[105b] *Petroleum Z.*, 1933, **29**, 5; *Chem. Abs.*, 1933, **27**, 3592.

Duncan, Ott and Reid[106] have shown that when a dilute (0.3*N*) aqueous solution of cupric acetate is agitated with a dilute solution of a mercaptan in benzene insoluble cuprous mercaptide is immediately formed. These cuprous mercaptides react slowly with sulphur to yield insoluble copper sulphide, the analysis of which indicated it to be cupric sulphide, but which from its formation should be cuprous sulphide. The reactions with copper acetate, therefore, may be represented by:

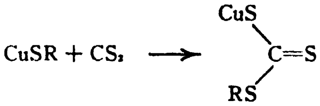
$$2Cu(C_2H_3O_2)_2 + 4RSH \longrightarrow 2CuSR + 4HC_2H_3O_2 + (RS)_2$$



$$2CuSR + 2S \longrightarrow 2CuSR.SR \longrightarrow \begin{matrix} CuS \\ | \\ CuS \end{matrix} + (RS)_2$$

The copper mercaptides obtained by the above method were all insoluble in water and in alcohol; those from normal mercaptans and from isopropyl and secondary butyl mercaptans were insoluble in ether and benzene, while the mercaptides from the higher secondary mercaptans were soluble. Light caused the derivatives of the secondary mercaptans to darken in color but did not affect those of the primary mercaptans. No basic copper mercaptides similar to the basic lead mercaptides were obtained.

Cuprous mercaptides also react readily with carbon disulphide to yield reddish thiocarbonates, which are much more soluble in benzene-carbon disulphide mixtures than the parent mercaptides are in benzene. The chemical properties of these thiocarbonates indicate very clearly that they are produced according to the reaction:



The benzene solutions of the cuprous derivatives of n-amyl and higher mercaptans often form jellies on standing, a change less likely to occur with the derivatives of secondary mercaptans.

ADSORPTION OF MERCAPTANS BY METALLIC SULPHIDES AND OTHER SUBSTANCES

As pointed out above, lead sulphide appears to have the property of adsorbing mercaptans from sour gasolines. In addition to lead sulphide, other sulphides, such as those of copper, tin, cadmium and arsenic, have been shown to possess the same property.[107]

Slagle and Reid[108] have investigated the adsorption of normal mercaptans, ranging from methyl to nonyl, from benzene solutions by cupric sulphide and other adsorption agents. The sulphides of copper and other metals were found to be adsorbents for normal mercaptans, though the proportion of mercaptan adsorbed varied widely with the different sulphides. Cupric compounds in general were good adsorbents, basic cupric carbonate being the best. Some of the results of duplicate experiments made by these investigators, using 50 cc. of a solution of n-butyl mercaptan (corresponding to 0.5 per cent sulphur by weight) and 0.5 gram of adsorbent, are given in Table 94.

TABLE 94.—*Removal of n-Butyl Mercaptan from Benzene.*

Adsorbent	Mercaptan Removed —Per Cent—	
Basic cupric carbonate	99.8	100
Cupric hydroxide	99.8	99.9
Cupric sulphide	65.0	66.0
Copper (precipitated powder)	50.1	50.6
Mercuric sulphide (black)	28.4	25.0
Lead sulphide	25.8	27.2
Antimony sulphide (red)	13.3	14.5
Cadmium sulphide	10.0	10.0
Barium hydroxide	5.4	5.4
Silica gel, activated	1.0	1.1
Antimony sulphide (black)	1.0	0.0
Iron powder	0.1	0.4
Kieselguhr	0.0	0.0

It was also determined that the percentage of mercaptan removed from solution depended upon (1) the concentration of the mercaptan in solution, and (2) the proportion of cupric sulphide used. One surprising result was that a single treatment with cupric sulphide removed only slightly less mercaptan than when the same weight of sulphide was used but applied in four successive treatments. Later in the investigation it was found that a large portion of the primary mercaptans "removed" had been converted to disulphides, which may offer an explanation of these results.

In attempting to remove secondary mercaptans from solution by means of copper or cupric sulphide it was observed that a part of the copper was dissolved with the formation of cuprous mercaptides, and at the same time some disulphides were formed. This was especially true for secondary mercaptans containing five to eight carbon atoms per molecule. This reaction was noticed because of the change in color of the benzene solution, as the cuprous mercaptides from secondary mercaptans are soluble in that solvent. If the same reactions took place with normal mercaptans, the insoluble cuprous mercaptides would remain on the surface of the cupric sulphide without affecting the color of the benzene solution.

Low[109] suggested the use of lead sulphide in the refining of gasoline. The liquid is passed through a bed of the finely ground, dried sulphide. The lead sulphide is regenerated intermittently by treating with aqueous solutions of an alkali sulphide and drying at 230° F.

EFFECT OF OTHER REAGENTS ON MERCAPTANS

The effect of solutions, or suspensions, of a number of metallic salts and oxides on mercaptans dissolved in naphtha has been investigated by Borgstrom, Deitz and Reid.[110] The mercaptans used in this work varied from ethyl to amyl, and included both the primary and secondary. Copper acetate, mercuric acetate, and ammoniacal cupric sulphate all yielded sweet naphthas. With the first two salts there was actual removal of mercaptans from solution, while the last named effected oxidation of the mercaptan to disulphide.[111] With reagents such as mercuric oxide, copper oxide, and copper sulphate, which apparently form insoluble mercaptides, variable results were obtained. The acetates of sodium, calcium, barium, cobalt, zinc and iron produced little or no effect. Bismuth nitrate solution exhibited a greater degree of reactivity which may have been due to the nitric acid required in the preparation of the solution. Both neutral and acid solutions of cadmium chloride produced slight decreases in the mercaptan content of the naphthas. Sodium zincate solution, corresponding to the sodium plumbite solution, reacted to a greater extent with the lower mercaptans than with the higher. Sodium hydroxide completely removed the lower-boiling mercaptans, but less completely the higher-boiling ones. Increasing the concentration of the alkaline solution did not increase the solubility of the mercaptans.

---

[109] U. S. Patent 1,777,619, Oct. 7, 1930; assigned to Richfield Oil Co. of California; *Chem. Abs.*, 1930, 24, 6001.

[110] *Ind. Eng. Chem.*, 1930, 22, 245.

[111] The removal of mercaptans, or other sour sulphur compounds, from cracked distillates has been described also by Gray, U. S. Patent 1,825,861, Oct. 6, 1931; assigned to Gray Process Corp.; Morrell, U. S. Patent 1,827,537, Oct. 13, 1931; assigned to Universal Oil Products Co.; *Brit. Chem. Abs.* B, 1932, 714.

In continuing the work with metallic salts a single sample of naphtha was used for making solutions of fourteen different mercaptans, normal and secondary from propyl to nonyl, and these solutions were treated with all the inorganic reagents which gave promise of a sweetening reaction.[112] The reagents were principally copper salts although three oxidizing agents, potassium permanganate, potassium dichromate, and potassium ferricyanide, were included. Of all the reagents only mercuric acetate yielded a sweet naphtha.

The steam distillation of naphtha, containing mercaptans volatile with steam, in the absence or presence of caustic soda solutions, did not appreciably lower the mercaptan content. Solutions of cupric sulphate or cupric acetate reduce the mercaptan content in proportion to the quantity of the salt employed.[113]

Various naphthas, having wide differences in boiling ranges and gravities, and to which mercaptans had been added, were steam distilled in the presence of solutions of copper salts alone or copper salts and sodium hydroxide.[114] Although some of the distillates were sweetened they still contained sulphur,—in some instances as much as 60 per cent of the added sulphur, part of which was in the form of disulphide.

The use of various salts, particularly cupric sulphate, as refining agents was discussed by Kalichevsky and Stagner.[115]

RECOVERY OF MERCAPTANS FROM PETROLEUM DISTILLATES

As previously pointed out there are very few methods for the actual recovery of mercaptans as such from petroleum distillates. Washing the distillate with sodium hydroxide solution does not extract all, as only part of the higher-boiling mercaptans are removed. Wendt[116] suggested the use of an alcoholic solution of sodium plumbite as a means of removing mercaptans, while Vesselovsky and Kalichevsky[116a] used alcoholic solutions of sodium or potassium hydroxide.

In recovering the mercaptides from the caustic soda solutions used in washing sour distillates, it is, of course, possible to liberate the free mercaptans by the addition of an acid. This method, however, also liberates hydrogen sulphide along with the mercaptans. Birch and Norris[117] took advantage of the fact that the mercaptans are weaker acids than hydrogen sulphide and that their salts are more easily hydrolyzed to obtain the mercaptans, free of hydrogen sulphide, by distillation of spent caustic soda solution. Along with the mercaptans disulphides also come over.

[116] U. S. Patent 1,658,505, Feb. 7, 1928; *Chem. Abs.*, 1928, **22**, 1233.
[116a] *Loc. cit.*
[117] *J.C.S.*, 1925, **127**, 898.

On the distillation of the spent caustic soda solution, used in washing a fraction representing the first 36 per cent (by volume) of a Persian crude oil, a mixture of mercaptans and disulphides was obtained. By washing this mixture with potassium hydroxide solution separation of these two classes of compounds was effected. Acidifying the potassium hydroxide solution liberated the free crude mercaptans. These crude mercaptans consisted of 55 to 60 per cent isopropyl mercaptan, 18 per cent isobutyl mercaptan, about 9 per cent of ethyl mercaptan, the intermediate fractions and a high-boiling residue accounting for the remainder. From the mixture of disulphides, obtained after separation of the mercaptans with potassium hydroxide, diethyl, diisopropyl and diisobutyl disulphides were isolated. In order to show the presence of these disulphides in the corresponding fractions it was necessary first to reduce them to the mercaptans (by means of zinc dust and glacial acetic acid) and to identify these.

As disulphides are insoluble in caustic soda solutions their presence along with mercaptans is explained in the following manner: The distillate used contained, in addition to mercaptans, both hydrogen sulphide and elemental sulphur. When this distillate was washed with caustic soda solution some sodium polysulphide was formed and remained in the aqueous layer, giving it a deep yellow color. On distillation of the spent caustic soda solution the sodium mercaptides reacted with the polysulphides to yield disulphides.[118]

The reclaiming of spent sodium hydroxide solutions by removing the sulphur compounds in the form of mercaptans, mercaptals, sulphides or disulphides, has been described by Mendius.[119] This is accomplished by the countercurrent scrubbing of the alkali solution with steam or with a dry sulphur-free gas.

It is interesting to note that phenolic substances may be obtained from spent doctor solutions.[119a] On acidifying the alkaline liquid with hydrogen sulphide (or sulphuric acid), an oily layer separates. This is distilled and the fraction boiling between 180° and 270° C. is treated with a reducing agent (e.g., iron and sulphuric acid) to convert the disulphides present to mercaptans. The oily material is then separated (by distillation) into two fractions which boil at 180° to 220° C. and 220° to 270° C., respectively, and these are subsequently oxidized with air, to change any mercaptans remaining to disulphides. After oxidation the fractions are again subjected to fractional distillation and phenols, practically free of disulphides, are said to be obtained.

Ferber[120] reported that the complete removal of sulphur compounds from the heavier distillates (transformer oils) can be effected by treatment with metallic sodium. The carbonaceous residue thus obtained, after acidifying with dilute hydrochloric acid followed by extraction with light petroleum ether and evaporation of the solvent, yielded a light yellow oil. This proved to be a mixture of disulphides from which, after reduction, amyl, heptyl and octyl mercaptans were obtained.

DISULPHIDES

While sulphur compounds of this type are known to exist in petroleum distillates, their actual isolation and utilization apparently have not been investigated, no doubt because they are very easily removed, together with other sulphur compounds, from the various distillates by treatment with sulphuric acid.[121] As pointed out in the discussion of the sweetening reaction, these sulphur compounds possess less disagreeable odors than the corresponding mercaptans which consequently are converted to disulphides in order to improve the odor of the lower-boiling distillates, such as gasoline or kerosene.

---

[118] For the reaction of sulphur and sodium ethylmercaptide, see Böttger, *Ann.*, 1884, 223, 348. For the reaction of alkalimercaptides and sodium polysulphides, see Holmberg, *Ann.*, 1908, 359, 81.

[119] *Refiner*, 1932, 11, 370.

[119a] Berry, Melvill and Banks, British Patent 386,977, 1933; *Chem. Abs.*, 1933, 27, 4665.

[120] *Z. angew. Chem.*, 1928, 41, 680; *Chem. Abs.*, 1928, 22, 4237.

The disulphides can, of course, be obtained from petroleum by indirect methods. For instance, Birch and Norris[117] in the extraction of mercaptans from light sour distillates obtained not only mercaptans but also disulphides, the latter being formed in secondary reactions taking place when the distillate was washed with caustic soda solutions. The mercaptans so obtained could also have been oxidized in alkaline solutions to disulphides. Ferber[122] also reported obtaining disulphides from the heavier distillates by the use of metallic sodium.

The relation between disulphides and mercaptans has been repeatedly pointed out, the former being an oxidation product of the latter. Disulphides, too, may be easily reduced to mercaptans.[122a] These relations can be represented by:

$$4RSH + O_2 \longrightarrow 2H_2O + 2RS.SR$$
$$RS.SR + H_2 \longrightarrow 2RSH$$

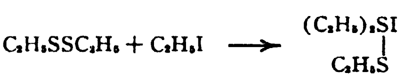
Wiezevich, Turner and Frolich[123] reported that ethyl mercaptan, at about 100° C., may be oxidized with air in the presence of iron, copper, iron sulphide or charcoal. Approximately 90 per cent yields of ethyl disulphide are said to be obtained under these conditions.

Using ethyl disulphide as an example, other typical reactions of disulphides are as follows: With dilute nitric acid this substance yields the compound $C_2H_5SO_2 \cdot SC_2H_5$. On reduction with zinc and dilute sulphuric acid this substance yields, first, the disulphide and, second, ethyl mercaptan. When dissolved in alcohol and reduced with zinc alone, zinc ethyl mercaptan and the zinc salt of ethylsulphuric acid are obtained:[124]

$$2C_2H_5SO_2SC_2H_5 + 2Zn \longrightarrow (C_2H_5S)_2Zn + (C_2H_5SO_2)_2Zn$$

When dissolved in alcohol and treated with sulphur, particularly in the presence of ammonia, a tetrasulphide $(C_2H_5)_2S_4$ is formed.[125]

The disulphides also react very slowly with alkyl halides, especially the iodides, to yield sulphonium compounds. A typical reaction would be:



$$C_2H_5SSC_2H_5 + C_2H_5I \longrightarrow \begin{array}{c}(C_2H_5)_2SI\\ |\\ C_2H_5S\end{array}$$

Such reactions are extremely slow but may be accelerated if carried out in the presence of mercuric iodide.[126] In this case, however, the free sulphonium iodide is not obtained but rather its double compound with mercuric iodide, as for example $(C_2H_5)_3S_2I \cdot 2HgI_2$.

[121] Wood, Lowy and Faragher, *Ind. Eng. Chem.*, 1924, **16**, 1116; Wood, Sheely and Trusty, *Ind. Eng. Chem.*, 1926, **18**, 169; Wright, *J. Inst. Pet. Tech.*, 1929, **15**, 214.

[122] *Loc. cit.*

[122a] For the application of this reaction to the refining of gasoline-containing distillates, see Morrell, U. S. Patent 1,920,270, Aug. 1, 1933; assigned to Universal Oil Products Co.; *Chem. Abs.*, 1933, **27**, 4918. Also French Patent 736,834, 1932; *Chem. Abs.*, 1933, **27**, 1499.

[123] *Ind. Eng. Chem.*, 1933, **25**, 295.

[124] Earlier workers considered that two oxidation products were obtained, a disulphoxide, $C_2H_5SO \cdot OSC_2H_5$, and the ethyl ester of ethylthiosulphonic acid, $C_2H_5SO_2 \cdot SC_2H_5$. The latter formula appears to be the more generally accepted. See Saizew and Lukaschweitz, *Z. für Chemie*, 1868, 641; Pauly and Otto, *Ber.*, 1878, **11**, 2073; Hinsberg, *Ber.*, 1908, **41**, 2836, 4294; Smiles and Gibson, *J.C.S.*, 1924, **125**, 176; Miller and Smiles, *J.C.S.*, 1925, **127**, 224.

[125] Holmberg, *Ber.*, 1910, **43**, 222.

[126] Hilditch and Smiles, *J.C.S.*, 1907, **91**, 1394.

As the disulphides possess boiling points much higher than the corresponding mercaptans and less disagreeable odors, there is the possibility of their use as solvents. Ethyl disulphide, for example, has been mentioned as a solvent for rubber, as well as for resins produced from xylenol and sulphur monochloride.[127]

ORGANIC SULPHUR COMPOUNDS

In addition to the mercaptans which appear in the various distillates from petroleum crude oils, particularly from high sulphur crudes, a large number of different sulphur compounds have been isolated. The particular types of compounds differ with the locality from which the crude oil is obtained. Such an immense amount of work has been done on the isolation of these compounds, that it is only possible to give a very brief review of some of it.[128]

THIOETHERS

Mabery and Smith[129] showed the presence of thioethers in petroleum in the following manner: The fraction of an Ohio crude oil boiling between 200° and 300° C. was extracted with concentrated sulphuric acid and the acid extract neutralized with lead carbonate or calcium hydroxide. On evaporation a salt separated which was then mixed with water and steam-distilled. A light yellow oil was obtained, and the portion of this boiling between 80° and 190° C. was fractionated at 100 mm. The fraction boiling from 80° to 90° C. contained no sulphur compounds, but the other fractions yielded crystalline products on treatment with an alcoholic solution of mercuric chloride. Analyses of the mercury precipitates indicated the presence of ethyl, propyl and butyl sulphides. No thiophenes or mercaptans were detected. Charitschkoff[130] also showed the presence of thioethers in Grosny naphtha by means of mercuric chloride. By diluting the sludge obtained in the refining of Persian petroleum, removing the separated oil and then extracting the aqueous layer with chloroform, Thierry[131] obtained an oil containing a large number of sulphur compounds. From the low-boiling fractions he was able to isolate methyl ethyl sulphide, and another compound which was either methyl propyl or methyl isopropyl sulphide.

CHEMICAL PROPERTIES OF THE THIOETHERS

The property of thioethers of forming addition compounds with mercuric chloride has served as a means of identifying some of the sulphur compounds in the sulphuric acid extract obtained in refining various crude petroleum oils. Other metallic halides, such as mercuric iodide, titanium tetrachloride and platinic chloride, react similarly. The thioethers, however, form addition compounds with other substances. For example, ethyl sulphide when heated at 150° C. in a sealed tube with sulphur yields a mixture of the di-, tri-, tetra-, and (possibly) penta-sulphides.[132] Bromine also forms addition products, such as $(C_2H_5)_2SBr_2$, which may be converted to the corresponding iodine derivatives by treatment with potassium iodide.[133]

This reaction with bromine has served as the basis for the estimation of thioethers in benzene, or other hydrocarbon solvent which is free of unsaturated hydrocarbons.[134] The solution of thioether is treated with bromine water, the excess bromine removed by the addition of potassium iodide, and iodine liberated is reduced with sodium thiosulphate. Hydrogen bromide is then extracted from the benzene solution with water and titrated with a dilute (0.05*N*) alkaline solution. The hydrogen bromide is formed as a result of the hydrolysis of the bromine addition product.[135] The reactions involving the formation of this addition product and its hydrolysis are:

$$R_2S + Br_2 \longrightarrow R_2SBr_2$$
$$R_2SBr_2 + H_2O \longrightarrow R_2SO + 2HBr$$

An interesting class of compounds, however, are those designated sulphonium (to show the analogy to ammonium compounds) and prepared by the interaction of the thioethers with alkyl iodides. To illustrate, methyl diethyl sulphonium iodide is formed when a mixture of ethyl sulphide and methyl iodide is allowed to stand for 2 to 3 days,[136] thus:

$$(C_2H_5)_2S + CH_3I \longrightarrow CH_3(C_2H_5)_2SI$$

The sulphonium compounds react with silver oxide and water to yield corresponding sulphonium hydroxides, which are strong bases and from which various salts may be prepared:

$$(C_2H_5)_3SI + AgOH \longrightarrow AgI + (C_2H_5)_3S.OH$$

Mild oxidizing agents, such as nitric acid of specific gravity 1.2, convert the thioethers to sulphoxides, and with more vigorous oxidizing agents the sulphone is obtained.[137] It is also possible to oxidize the sulphoxide to the sulphone, thus:

$$2(C_2H_5)_2S + O_2 \longrightarrow 2(C_2H_5)_2SO \text{ (sulphoxide)}$$
$$(C_2H_5)_2S + O_2 \longrightarrow (C_2H_5)_2SO_2 \text{ (sulphone)}$$

The sulphoxide is easily reduced with zinc and sulphuric acid to the thioether. Ethyl sulphoxide has been suggested as a plasticizer for pyroxylin.[138]

Two general methods of synthesizing thioethers are: the interaction of (1) alkyl halides and potassium (or sodium) sulphide, and (2) alkyl halides and potassium (or sodium) mercaptides. The latter method is analogous to that employed to make ethers, and permits the preparation of mixed thioethers (that is, thioethers containing two different alkyl radicals):

$$(1)\quad 2C_2H_5Cl + K_2S \longrightarrow 2KCl + (C_2H_5)_2S$$
$$(2)\quad CH_3I + C_2H_5SNa \longrightarrow NaI + CH_3SC_2H_5$$

Sabatier and Mailhe[139] reported that the passage of ethyl mercaptan over a cadmium sulphide catalyst at 320° to 330° C. resulted in the formation of ethyl sulphide and hydrogen sulphide. At a higher temperature (380° C.) ethylene and hydrogen sulphide were the main products. Wiezevich, Turner and Frolich[140] found that 45 to 55 per cent yields of thioethers were obtained from mercaptans at 350° C. when using a catalyst consisting of cadmium sulphide, zinc sulphide, and aluminum oxide.

The thioethers, particularly those derived from low molecular weight paraffins, are liquids possessing boiling points lying between those of the corresponding mercaptans and disulphides. See Table 95.

TABLE 95.—*Boiling Points of Sulphur Compounds.*

	Mercaptan ° C.	Thioether ° C.	Disulphide ° C.
Methyl	5.8	37.5–38	116–118
Ethyl	37	92–93	153–153.5
n-Propyl	67–68	141.5–142.5	192.5
n-Butyl	97–98	182	—

A possible application of thioethers is as solvents for various materials. Wiezevich, Turner and Frolich[141] have pointed out that these compounds dissolve rubber, as well as resins such as abietic acid, paracumaron, petroleum resin, and m- and p-cresol-sulphur chloride resins, and that cellulose nitrate is soluble in mixtures of ethyl alcohol and ethyl sulphide or methyl alcohol and propyl sulphide.

THIOPHANES

The thiophanes were isolated by Mabery and Quayle[142] from fractions of a Canadian petroleum using an alcoholic solution of mercuric chloride. The lower members of the series formed crystalline precipitates while viscous or oily masses were obtained from the higher members. The thiophanes were obtained in the free state by treating the mercuric chloride derivatives with hydrogen sulphide. The general formula for this series is $C_nH_{2n}S$ and hence they correspond to hydrothiophenes, thiophene having the formula C_4H_4S. They were therefore called thiophanes.

The thiophanes isolated, and some of their physical properties, are given in Table 96.

TABLE 96.—*Physical Properties of Thiophanes Isolated from a Canadian Petroleum.*

		B.P. at 50 mm. ° C.	Sp. Gr. (20°)	n_D
Hexylthiophane	$C_6H_{12}S$	55–57	—	—
Heptylthiophane	$C_7H_{14}S$	74–76	0.8878	1.468
Octylthiophane	$C_8H_{16}S$	81–83	0.8929	1.4860
iso-Octylthiophane	$C_8H_{16}S$	94–96	0.8937	—
Nonylthiophane	$C_9H_{18}S$	106–108	0.8997	1.4746
Decylthiophane	$C_{10}H_{20}S$	114–116	0.9074	1.4766
Undecylthiophane	$C_{11}H_{22}S$	128–130	0.9147	1.480
Tetradecylthiophane	$C_{14}H_{28}S$	168–170	0.9208	1.4892
Hexadecylthiophane	$C_{16}H_{32}S$	184–186	0.9222	1.4903
Octadecylthiophane	$C_{18}H_{36}S$	198–202	0.9235	1.4977

These thiophanes are characterized by the ease with which they react. They are readily oxidized by potassium permanganate or by chromic acid to sulphones, all of which are thick heavy oils having high boiling points and specific gravities greater than that of water. They react with ethyl iodide to form addition compounds, $C_nH_{2n}S \cdot C_2H_5I$. These latter compounds when warmed with silver oxide and water are converted to the corresponding hydroxides which show an alkaline reaction. The thiophanes also react violently with bromine with the evolution of hydrogen bromide in quantities equivalent to the bromine added. The chloroplatinates of the thiophanes are heavy, viscous oils.

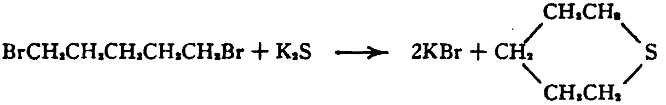
Thierry[143] has isolated both tetramethylene sulphide and pentamethylene sulphide from the sludge obtained by treating Persian petroleum with sulphuric acid.

While tetrahydrothiophene and the other thiophanes were not well known at the time Mabery and Quayle reported their existence in petroleum distillates, some of them (tetrahydrothiophene and pentamethylene sulphide) were later synthesized by von Braun and Trümpler.[144] Their method was to allow potassium sulphide to react with the dibromide of the corresponding hydrocarbon. Pentamethylene sulphide, for example, was made from 1,5-dibromopentane and potassium sulphide, thus:



These thiophanes are liquids possessing very disagreeable odors. Tetrahydrothiophene boils at 119° C., and pentamethylene sulphide at 141° C.

In a similar manner Grischkevich-Trokhimovski[145] has prepared thiophanes containing three, four, five and six carbon atoms in the nucleus. These thiophanes exhibit the general properties of organic sulphides, i.e., they form sulphones, sulphonium compounds, dibromides (which are unstable), and addition products with mercuric chloride.

The reactions of two thiophanes, tetramethylene and pentamethylene sulphides, were later investigated by Bost and Conn.[146] The solvents used in this work were n-heptane and three different naphthas. From both heptane and naphtha solutions these thiophanes yield crystalline precipitates with mercuric chloride; oxidizing agents such as nitric acid, potassium permanganate, and hydrogen peroxide convert them to sulphones; methyl iodide reacts with them to yield the corresponding addition products; and bromine and mercuric iodide form unstable products with the thiophanes. Comparing the reactions of the thiophanes with those of ethyl sulphide and thiophene, under the same conditions, the indications are that the thiophanes more closely resemble alkyl sulphides than thiophene.

The behavior of trimethylene sulphide in heptane and naphtha solutions was studied also.[146a] This thiophane gave stable derivatives with mercuric chloride and methyl iodide. Sulphones were obtained on treatment with potassium permanganate or 30 per cent hydrogen peroxide. With bromine it yielded an orange-yellow precipitate, which was unstable, decomposing even at —15° C. Highly polymerized compounds resulted from the action of nitric or hydrochloric acid on trimethylene sulphide, which distinguishes it from tetra- and penta-methylene sulphides. Like these higher members, however, it resembles alkyl sulphides in chemical properties more than thiophene.

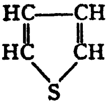
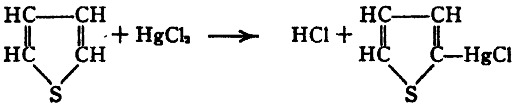
OTHER SULPHUR COMPOUNDS

The presence of thiophene in petroleum oils has been reported by a number of workers. Edeleanu and Filiti[147] found that certain Rumanian crude oils gave the characteristic thiophene reaction with isatin and sulphuric acid, and Meyer and Nahnsen[148] showed the presence of this same compound in the naphtha from some German crude oils.

In its chemical properties thiophene,



resembles benzene more closely than it does the aliphatic thioethers. For example, halogens react with it to yield substitution products rather than to saturate the double bonds or to add halogen to the sulphur. Formulas of representative compounds of this type are C_4H_3BrS and $C_4H_2Cl_2S$. Nitric acid and sulphuric acid react with thiophene to yield nitro-compounds and sulphonic acids, respectively. The reaction with mercuric chloride differs from the corresponding reaction of aliphatic thioethers and mercuric salts in that one chlorine atom is eliminated as hydrogen chloride and the mercury becomes attached to the thiophene nucleus, thus:



According to McKittrick,[149] the HgCl radical enters the *a* or 2 position if that is unoccupied, otherwise the *β* or 3 position; the latter reaction is much slower than the former. Both types of derivatives are soluble in alcohol and other organic solvents. If both *a* positions are unoccupied, then a mixture of the *a*-mono- and *a,a′*-dimercuric chloride derivatives is formed. These dimercuric chloride compounds are extremely insoluble in all common organic solvents.

SULPHUR COMPOUNDS IN CRACKED DISTILLATES

The types of organic sulphur compounds thus far mentioned have been those occurring in crude petroleum oil or its distillates. Some of the same types, however, have been found in the cracked distillates from petroleum oils. For example, Tomekichi Kan,[150] using a cracked distillate having a density of 0.834, an iodine number of 48.02, and a sulphur content of 1.15 per cent, found that on agitating this oil with an alcoholic solution of mercuric chloride the compounds, $C_2H_6SHgCl_2$ and $C_4H_{10}SHgCl_2$, were precipitated. Along with these substances similar compounds of their higher homologues and also polymerization products were obtained. Dudenko[150a] reported a pressure distillate (boiling range, 40° to 231° C.) containing 0.005 per cent elemental sulphur, 0.01 per cent sulphur as hydrogen sulphide, 0.004 per cent as mercaptans, 0.006 per cent as disulphides, 0.003 per cent as thioethers and 0.038 per cent as other sulphur compounds.

Some information about the sulphur compounds occurring in a naphtha obtained by cracking the fuel oil from Midway (California) crude petroleum has been given by McKittrick.[149] The sample of naphtha was subjected to a series of fractional extractions using, first, liquid sulphur dioxide at —20° to —30° C.; second, aniline at —10° to —20° C.; and finally ethylene glycol diacetate also at —10° to —20° C. From 212 liters of the original naphtha, having a specific gravity of 0.786 at 15° C. and a sulphur content of 1 per cent, 13.6 liters of oil extract, having a specific gravity of 0.900 at 15° C. and 5.5 per cent sulphur, were obtained. This extract represented 40 per cent of the total sulphur in the original distillate; of the rest, 25 per cent remained in the residual oil from the liquid sulphur dioxide treatment and 35 per cent in the various low sulphur fractions obtained on extraction with aniline or with ethylene glycol diacetate and which were discarded. The oil extract was distilled up to 160° C. at atmospheric pressure and then the distillation completed at 120 mm. pressure, taking cuts every 2.5° C.

The sulphur compounds identified in these fractions were thiophene and its homologues. These were precipitated as the mercuric chloride derivatives by dissolving the different fractions in small quantities of alcohol and adding an aqueous solution of mercuric chloride, together with sodium acetate. The mercury derivatives were separated by their solubility in hot alcohol, and the sulphur compound liberated by decomposing these derivatives with 6*N* hydrochloric acid. The sulphur compounds thus isolated and identified were: thiophene, 2-methyl- and 3-methylthiophene, 2,3-dimethylthiophene, 3,4-dimethylthiophene, 2-ethyl- and 3-ethylthiophene. All of these compounds were found in the fractions boiling below 160° C. at atmospheric pressure.

McKittrick also attempted to isolate some of the sulphur compounds which were present in the sludge obtained by the low temperature acid treating of cracked naphtha. He isolated two compounds which appeared to contain eight and eleven carbon atoms, respectively, although their structures were not determined. Their chemical properties, however, were very similar to those of compounds isolated by Mabery and Quayle[142] from the sludge formed in treating Canadian kerosene.

USES OF SULPHUR COMPOUNDS FROM PETROLEUM

One use for the mineral oil products possessing a high sulphur content is as a denaturant for ethyl alcohol, under the trade name *Alcotate,* to replace methyl alcohol.[151] The specifications for this product are as follows: Specific gravity at 15.5° C. must not be less than 0.850. Sulphur content must be not less than 4.5 per cent. No added hydrogen sulphide, carbon disulphide or elementary sulphur is to be present. Upon distillation 20 per cent must distil over at 175° C., 50 per cent at 195° C., and 90 per cent at 245° C. Alcotate must mix with an equal volume of 95 per cent alcohol and show no separation. The addition of 8 cc. of water to 25 cc. of a 1.5 per cent solution of Alcotate in 95 per cent alcohol should produce no more turbidity than that shown by the addition of 1.5 grams of chemically pure lead acetate to 25 cc. of water.

Highly refined petroleum oils have been used as insecticides for certain insects on nearly every type of orchard crop. The oil emulsions used generally have an oil concentration of about 60 to 90 per cent and before application are diluted with water to the range from 0.75 to 5.0 per cent. Oils containing a high percentage of organic sulphur possess a high fungicidal as well as insecticidal value.[152]

---

[151] *Petroleum Z.*, March 18, 1931, *Motorenbetreib und Maschinen-Schmierung,* 15. *Cf. Ind. Eng. Chem.*, 1931, 23, 2.

A product called *Cal-Odorant No. 3,* developed by the Standard Oil Co. of California, is a mixture of hydrocarbons and sulphur compounds and is marketed for odorizing natural gas.[153] About 3 gallons of this odorant per million cubic feet of gas are required. This application of sulphur compounds is similar to the use of mercaptans in manufactured gas. Organic sulphur compounds, which are intended as odorants for the detection of gas leakage, can be prepared either by sulphonating hydrocarbons with sulphuric acid at 100° C. followed by cracking, or by cracking the waste acid obtained in the refining of cracked distillates.[154]

The addition of a small proportion of carbon bisulphide, ethyl mercaptan or ethyl sulphide to a non-cutting oil in an oil well or pipe line to prevent accumulation of solid matter has been proposed.[155] (By non-cutting oil is meant an oil which does not possess emulsifying powers.) These sulphides act as emulsifying agents and assist solid materials to be carried along by the oil stream rather than permitting them to deposit on the walls of the casing or in other places.

Mixtures of sulphur compounds, such as n-propyl disulphide, methyl disulphide, benzyl sulphide or disulphide, carbon disulphide or thiocarbonates, with vegetable protein material have been proposed as adhesives.[155a] The stabilization of chlorinated hydrocarbons, e.g., carbon tetrachloride, trichloroethylene or tetrachloroethylene, with a small proportion of butyl mercaptan is suggested by Stewart and DePree.[155b]

THERMAL DECOMPOSITION OF SULPHUR COMPOUNDS

Some information regarding the thermal decomposition in the vapor phase of sulphur compounds of the types representative of those present in petroleum has been given by Faragher, Morrell and Comay.[156] These workers investigated the decomposition of pure compounds both alone and dissolved in petroleum oils. Most of their investigations wese carried out at 496° C. (925° F.), which is within the temperature range used industrially for the cracking of petroleum oils.

The pure compounds, or their solutions in naphtha, were allowed to flow directly into a reaction tube, where they were flashed into a vapor. The average temperature of the tube was 496° C. The products of decomposition were passed through a condenser, and both the liquid condensate and the uncondensed gases analyzed.

Disulphides, such as the ethyl, n-propyl, and isoamyl, yielded hydrogen sulphide, mercaptans, thioethers and thiophene or its derivatives, together with some saturated and unsaturated gaseous hydrocarbons. From ethyl sulphide only hydrogen sulphide, mercaptans and the hydrocarbon gases were obtained, while isoamyl sulphide yielded the same products together with some thiophene derivatives and a small quantity of hydrogen (about 0.5 per cent) in the gases. Isoamyl mercaptan yielded elemental sulphur, a large quantity of hydrogen sulphide, a tarry residue, and hydrocarbon gases, no sulphides or thiophene derivatives being detected.

Isoamyl disulphide, n-propyl sulphide, and isoamyl sulphide were dissolved

in a naphtha, obtained from Pennsylvania crude petroleum, and the vapors of these solutions passed through the reaction tube at 496° C. The main products of the reaction appeared to be elemental sulphur, hydrogen sulphide, and mercaptans. Substitution of elemental sulphur for the sulphur compounds yielded hydrogen sulphide as the only reaction product. The heat treatment of a naphtha solution of thiophene, at either 496° C. or 871° C. failed to show any thermal decomposition of this substance, though there was some loss of naphtha due to cracking at the latter temperature.

The thermal decomposition of aliphatic mercaptans dissolved in various solvents was investigated by Malisoff and Marks.[157] The solvents used were benzene, a mixture of n-heptane with 2,2,4-trimethylpentane, and a stable straight-run gasoline (end point about 150° C.) which was practically free of sulphur. The mercaptans used were n-propyl, n- and iso-butyl, n- and iso-amyl, and benzyl mercaptan. The temperatures varied over a range from about 300° to 475° C. The percentage decomposition increased with increasing temperatures, and also with increased time of passage of the gases through the heated zone. Branched-chain mercaptans were less stable than the corresponding straight-chain isomers, though only markedly so at the higher temperatures (particularly around 475° C.). Benzyl mercaptan was less stable than any of the lower aliphatic mercaptans. The solvent also appeared to exert some influence as benzene, compared to the straight-run naphtha, promoted decomposition, particularly of n-amyl mercaptan. The decomposition of this latter mercaptan was depressed by the addition of carbon dioxide or hydrogen. All the mercaptans on decomposition yielded hydrogen sulphide and an olefin.

Butyl sulphide dissolved in benzene (0.025 to °.3 molar solutions) was subjected to temperatures of 400° to 515° C. by Malisoff and Marks,[157a] the period of heating varying from 5 to 55 seconds. The products of the reaction were hydrogen sulphide and mercaptans. No decomposition occurred at 400° C., moderate decomposition at 500° C., and at 515° C. with 30 seconds exposure only 20 per cent conversion of the sulphide was obtained. In the presence of a large proportion of hydrogen sulphide, thiophene and free sulphur were formed in addition to the products mentioned. The reaction is not unimolecular and is catalyzed by glass surfaces or by aluminum oxide. Comparison of the rates of decomposition in benzene and in n-heptane solutions indicated benzene probably accelerated the reaction and that n-heptane may be an inhibitor. Butyl sulphide appeared to be more stable than the corresponding mercaptan.

Trenner and Taylor[157b] reported that the thermal decomposition of ethyl mercaptan or sulphide, at 380° to 410° C. under 50 to 440 mm. pressure, yielded hydrogen sulphide, ethylene and polysulphides. An intermediate product, boiling at 48° to 49.5° C. and possibly a dimercaptan ($C_2H_5SH{=}SHC_2H_5$), was isolated in both instances.

In studying the cracking of a high sulphur (3.6 per cent) gas oil, particularly with reference to the formation of carbon disulphide, Holtz[158] observed that no carbon disulphide was obtained at 649° C., a small quantity at 732° C., and at 982° C. a large quantity of this material was formed. When a sulphur-free oil was cracked at about 850° C. in the presence of a gas containing hydrogen sulphide, no carbon disulphide was formed unless the hydrogen sulphide was present in large proportions. Even in the absence of carbon disulphide formation, a large disappearance of hydrogen sulphide during the cracking operation was noted. Furthermore, on passing hydrogen sulphide over sugar charcoal at 850° C., neither hydrogen sulphide nor carbon disulphide could be discovered at first in the exit gas; after a time, a gradually increasing quantity of hydrogen sulphide could be detected; and finally, after a still further time interval carbon disulphide was found among the reaction products. The charcoal at the end of the experiment contained 2.8 per cent sulphur.

These phenomena are attributed to the formation of a solid carbon-sulphur complex. It is suggested that the surfaces of carbon when exposed at the temperatures used in gas-making to gases containing sulphur, first absorb sulphur from these gases, which aids in the further decomposition of sulphur compounds. The ability to absorb sulphur gradually decreases and a degree of saturation is approached before carbon disulphide is evolved. Although sulphur appears to resemble oxygen in forming a complex with carbon no exact analogue of carbon monoxide was isolated.

Rosen and Lieber [158a] described a process for the conversion of organic sulphur compounds to hydrogen sulphide by passing the gases over a catalyst consisting of ferrous sulphide and a promoter, the latter being an oxide or sulphide of the metals of Groups III or VI of the Periodic System. The temperatures employed varied from 337° to 482° C.

EFFECT OF REFINING AGENTS ON SULPHUR COMPOUNDS

The literature dealing with the refining of petroleum distillates, particularly those distillates containing a high percentage of sulphur compounds, is voluminous. No attempt is made here to review such a vast field exhaustively, but rather to indicate some of the fundamental physical and chemical properties of the sulphur compounds which are the bases for such methods.

Solvent extraction [159] of sulphur compounds is the most common procedure for their removal, and sulphuric acid is apparently the best solvent.[160] In addition to its action as a solvent this acid also exerts other effects, for example, its oxidizing action on mercaptans. The disadvantages connected with its use, particularly with cracked distillates, are that it either polymerizes the unsaturated hydrocarbons or reacts with them to form alkylsulphuric acids. Refining at low temperatures, 3° C. or lower, has been suggested as a means of overcoming these latter two effects.[161] Gary [161a] recommended sulphur trioxide dissolved in liquid carbon dioxide.

Petroleum oils, possessing a high-sulphur content, are reported to be substantially desulphurized by liquid ammonia.[161b] The oil is mixed with liquid anhydrous ammonia (under pressure) in the presence of catalysts, e.g., metallic sodium, potassium, calcium or barium. Some of the ammonia is converted to ammonium sulphide, or complex ammonium sulphur compounds, which may be recovered from the oil by extraction with water or by heating the oil with ammonia vapor and steam. Oxidation of the ammonium compounds yields ammonium sulphate. The latter may be obtained directly by treating the oil with liquid ammonia and ozone or ammonium persulphate.

A large number of solid adsorption agents have been proposed for the removal of sulphur compounds.[162] Included among these are: fuller's earth, silica gel,[163] aluminum oxide, aluminum chloride, and mercuric chloride or acetate. Holmes[164] reported that metallic sulphides disseminated throughout "red gels" (made by mixing dilute solutions of ferric chloride and sodium silicate) are good adsorbents for sulphur compounds of the thiophene type. Of the sulphides investigated, cupric sulphide appeared to be the best.

Oxidizing agents have been suggested as reagents for removing sulphur compounds. The reactions probably involved are the oxidation of thioethers to sulphones, which are soluble and can be removed by washing with water, and of other sulphur compounds, such as mercaptans, to sulphonic acids, removed by washing with an alkaline solution. Thus, using pentamethylene sulphide as an example of the thiophanes, Borgstrom, Bost and McIntire[165] have shown that when dissolved in naphtha it is almost completely removed by refluxing with permanganate solution, or by washing with sodium hypochlorite solution. Other oxidizing agents which have been proposed are oxygen, ozone, or ozonized oxygen.[166]

Wood, Lowy and Faragher[167] observed that solutions of sodium hypochlorite convert mercaptans to disulphides, but have little effect on other types of sulphur compounds. Birch and Norris,[167a] however, reported that alkyl sulphides are converted to sulphones by sodium hypochlorite solutions, and as the sulphones are soluble in water (solubility, of course, varies with the molecular weight) this permits extraction of sulphur compounds. Wood, Greene and Provine[168] also observed the desulphurizing effect of hypochlorite solutions on naphtha containing various sulphur compounds. This effect was dependent on the type and molecular weight of the sulphur compound, the degree of alkalinity of the hypochlorite solutions, the quantity of available chlorine, and the time and intensity of agitation of the hypochlorite solution and naphtha. All investigators are agreed that thiophene is not removed by hypochlorite solutions.

In the Frasch[169] process, high sulphur oils are heated with copper oxide, or a mixture of copper and lead oxides. Probably the sulphur compounds are not only oxidized by these metallic oxides with the formation of the corresponding metallic sulphides, but in addition the mercaptans react with these oxides to yield mercaptides, which decompose on heating to thioethers and metallic sulphides. The reactions with lead oxide, for example, may be represented as:

$$\mathrm{PbO + 2RSH \longrightarrow Pb(SR)_2 + H_2O}$$
$$\mathrm{Pb(SR)_2 \longrightarrow R_2S + PbS}$$

Additional suggestions of Frasch are reviewed in Kalichevsky and Stagner, "Chemical Refining of Petroleum," Chemical Catalog Co., Inc., New York, 1933, 264, and in Engler-Höfer, "Das Erdöl," Verlag von S. Hirzel, Leipzig, 1913, **3**, 546.

With some petroleums, a mixture of 70 per cent copper oxide, 15 per cent lead oxide, and 15 per cent iron oxide yields better results.[170] Also, passing the vapors of the petroleum distillate, together with steam, over iron ore effects a reduction of sulphur of over 80 per cent, accompanied by the evolution of large quantities of hydrogen sulphide. At the same time considerable cracking of the distillate takes place, and the pores of the contact mass become filled with carbon which can be only partially removed by steam. The use of a mixture of iron and copper oxides (obtained on burning pyrites of iron and copper) in a similar manner is described by Blagodorov.[171] Cross[172] has suggested desulphurizing and degumming the hydrocarbons produced by cracking by passing them, either in the liquid or vapor phase, first through a bed of a metal (or its oxide) and then through a bed of adsorbent clay, such as bentonite.

Kogerman[173] reported that metals, such as nickel or copper, are not satisfactory for the vapor-phase desulphurization of Esthonian shale-oil distillates. An effective procedure is the hydrogenation of such distillates at temperatures of 300° to 400° C., and at pressures of 900 to 1000 atmospheres. Guthke[173a] removed sulphur compounds from hydrocarbons by treatment with hydrogen at 100° to 300° C. in the presence of a metallic sulphide (nickel or molybdenum sulphide) and an activator, e.g., cobalt or chromium oxide. The applied pressure was less than that required for hydrogenation of the hydrocarbons. Pease, Keighton and Munro[173b] partially eliminated thiophene from benzene by hydrogenation at atmospheric pressure in the presence of mixed catalysts consisting of cobalt or chromium oxide or sulphide and molybdenum oxide or sulphide.

A method suggested for the elimination of sulphur compounds from industrial gases is scrubbing with an alcoholic solution of sodium hydroxide. In another procedure mixtures of hydrocarbon gases, or vapors, are desulphurized[174] by conducting them over a thorium or thorium oxide catalyst at a temperature of about 650° C. Promoters can be used, such as magnesium oxide, lead oxide, copper or nickel. In such a process the sulphur-containing substances are converted to hydrogen sulphide, which is then removed from the gaseous mixture. The catalytic mass is regenerated by air, steam or hydrogen.[175]

Lachman[176] has described a vapor-phase process for the removal of sulphur compounds in which the vapors of gasoline, or other petroleum distillates, are passed countercurrent to a concentrated solution of a metallic salt at temperatures ranging from 200° to 260° C. An example of such a reagent is an 80 per cent solution of zinc chloride to which 0.5 to 3.0 per cent zinc hydroxide has been added. To prevent evaporation or concentration of the solution steam or water may be added to the hydrocarbon vapors. Salts of other metals, such as those of cadmium, mercury, iron, cobalt, nickel, chromium, copper, manganese and aluminum, may be employed. Kubulnek[177] has reported that this method of treatment removes sulphur compounds which are rendered inactive by the doctor treatment, but which are reactivated under conditions existing in an internal-combustion engine and cause corrosion. He also pointed out the advisability of washing the petroleum distillate with 5 per cent sodium hydroxide solution before subjecting it to the Lachman process. Heating petroleum oils, under pressure, in the presence of metallic chlorides, particularly titanium chloride, is said to convert the stable sulphur compounds into sulphur derivatives which may be eliminated with sodium plumbite solution.[177a] Pretreatment with ferric chloride, to remove oxygenated compounds, was recommended.

Vaporizing petroleum hydrocarbons and subjecting them to the action of ultraviolet light in the absence of oxidizing gases but in the presence of a porous contact mass in which sulphur-containing condensation products are precipitated, is another proposed method.[177b] Egloff[177c] recommended the desulphurization of cracked hydrocarbon vapors with ozone in the presence of a silent electric discharge.

REACTIONS OF SULPHUR COMPOUNDS WITH METALS

Reactions with metals have been studied by Elgin, Wilder and Taylor[178] as a means for the removal of sulphur compounds from both straight-run and cracked naphthas. Two metals were employed, a reduced nickel oxide supported on kieselguhr, and a reduced iron catalyst containing potassium and aluminum oxides as promoters, which had been used for the synthesis of ammonia. Adsorption of sulphur compounds in the liquid phase was accomplished by agitating the naphtha with different weights of nickel. The amount of sulphur removed was proportional to the quantity of contact agent up to about 45 grams of nickel per 100 cc. of naphtha. From this point on, increasing the proportion of nickel gave only slightly greater sulphur removal, and under none of the conditions studied was complete removal of sulphur possible. Filtration of the naphthas through a column packed with the nickel yielded no better results than were obtained by agitation. A higher percentage of sulphur compounds, as shown in Table 97, was removed from cracked naphtha than from straight-run naphtha.

TABLE 97.—*Maximum Sulphur Adsorbed by Nickel from Liquid.*

Naphtha	Sulphur Content Initial	Sulphur Content Final	Sulphur Adsorbed
	Per Cent	Per Cent	Per Cent
Straight Run No. 1	0.410	0.210	46.0
Straight Run No. 2	0.278	0.165	40.7
Cracked No. 3	0.357	0.157	56.0

Nickel appears to adsorb certain sulphur constituents selectively from the naphthas, the quantity adsorbed being different for naphthas from different sources. For example, the mercaptans were completely removed from the cracked naphtha used but not from the straight-run naphthas. Sulphur compounds other than mercaptans were adsorbed in all cases. The adsorption appears to be irreversible, as no sulphur was removed by extraction of the used contact mass with sulphur-free naphtha. Reduced iron was very much less effective than reduced nickel.

[177b] Magnus, German Patent 500,718, 1927; *Chem. Abs.*, 1930, **24**, 4928.

[177c] U. S. Patent 1,803,964, May 5, 1931; assigned to Universal Oil Products Co.; *Brit. Chem. Abs.* B, 1932, 92.

[178] *Ind. Eng. Chem.*, 1930, **22**, 1284.

For the vapor-phase removal of sulphur compounds the vapors of the different naphthas were passed over the metals at 300° C., and the sulphur content of the condensed vapor determined at regular intervals. Sulphur removal was pronounced at first, but diminished until a steady state was reached, in which the reduction of sulphur was constant. The volume of naphtha vapor treated by the adsorbent before this steady state was attained, the percentage reduction of sulphur during this state, and the kinds of sulphur compounds removed appeared to depend upon the particular naphtha treated. All mercaptans, however, seemed to be removed. Sulphur is eliminated from distillates by this vapor-phase treatment in the form of hydrogen sulphide.

Redistillation of the naphthas treated in this way over fresh samples of the metals resulted in only very slight reduction of sulphur content. A third treatment did not further reduce the sulphur content. When hydrogen was added to the naphtha vapors (1 volume of hydrogen to 3.7 of vapor), a greater reduction of sulphur content was obtained, although the characteristics of the catalyst remained the same. Reduced iron, which is very effective in the synthesis of ammonia, was much less so than nickel for vapor-phase removal of sulphur.

Elgin,[179] in studying the adsorption of pure compounds from naphtha solutions by reduced nickel oxide, observed that mercaptans were removed to a larger extent than either alkyl sulphides or thiophene.

In the vapor-phase treatment of such naphtha solutions, with a nickel adsorbent (such as that described by Elgin, Wilder and Taylor) which had reached the steady state, alkyl mercaptans and sulphides seem to undergo a reaction evolving hydrogen sulphide, and the mercaptans seem to be more readily removed than the sulphides. Thiophene was not affected unless hydrogen was added to the naphtha vapors. Using a sulphur-free catalyst, thiophene sulphur can be removed, but the catalyst rapidly loses its activity.

Another proposed method is to heat the petroleum distillate in contact with precipitated, reduced copper, and then to filter off the excess copper and copper sulphide.[180] Sulphur compounds are removed as sulphides by subjecting the distillates to the action of tin, aluminum, copper, magnesium or their lower oxides followed by treatment with sodium zincate.[180a]

SULPHUR COMPOUNDS IN SHALE OIL

In discussing the sulphur compounds found in petroleum and its distillates, it is of interest to include a brief reference to those present in shale and shale oil.

Harding and Thordarson[181] have studied the distribution of sulphur in American (Colorado) oil shale. As a line of demarkation between coal and shale has never been sharply drawn, they used the methods of analysis which were in principle those employed by Parr and Powell[182] in their analyses of coal, and found the particular shale studied to contain:

	Per Cent
Total sulphur	1.373
Sulphate sulphur	0.0865
Sulphide sulphur	0.6375
Organic sulphur	0.649

---

[180] Feld, British Patent 332,910, 1929; assigned to Stadtberger Hütte A.-G.; *Chem. Abs.*, 1931, **25**, 521. *Cf.* Dittrich, *Brennstoff-Chem.*, 1933, **14**, 283; *Brit. Chem. Abs.* **B**, 1933, 819.

[180a] Benzol-Verband G.m.b.H., German Patent 570,876, 1933; *Chem. Abs.*, 1933, **27**, 4388.

[181] *Ind. Eng. Chem.*, 1926, **18**, 731.

[182] *Univ. Illinois Exp. Sta. Bull.*, 1919, **111**.

After extracting the shale with phenol its sulphur content was 1.368 per cent, indicating only 0.005 per cent resinic sulphur, a negligible quantity. The humus sulphur content, the difference between organic and resinic sulphur, was 0.644 per cent. Practically all of the sulphide sulphur was present as pyrites, marcasite, or both.

The portion of Kimmeridge shale oil volatile with steam, amounting to about 30 per cent of the crude oil, was investigated by Challenger, Haslam and Bramhall.[183] This fraction was treated successively with hydrochloric acid (1:3), sodium hydroxide (10 per cent), and a saturated solution of sodium hydrogen sulphite. These removed amines, phenols and ketones, respectively. The purified product was then dried and distilled first at atmospheric pressure (to a temperature of 180° C.) and then under vacuum (27 mm. pressure). Various fractions obtained during the distillation were investigated to identify sulphur compounds present. Table 98 shows the boiling ranges of the various fractions and the sulphur compound isolated from each.

TABLE 98.—*Sulphur Compounds Isolated from Shale Oil Fractions.*

B.P., ° C.	Sulphur Compound Found
75–93	Thiophene
109–117	2-Methylthiophene
134–138	2-Ethylthiophene and 2,3-dimethylthiophene
158–167	A thiophene derivative, either propyl, methylethyl or trimethyl

Dodonov and Soshestvenska[184] have shown that thiophene, 2-thiotolene, and 2,3-thioxene occur in the 170° to 180° C. fraction from Russian shale oil. The isolation of such compounds must be preceded by a very careful and tedious fractionation of an appropriate portion of the oil.

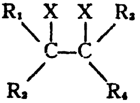
Chapter 20

Reactions of Olefins with Halogens. Olefin Dihalides and Their Derivatives

The olefin hydrocarbons as a class, and also all compounds possessing an olefinic linkage in their molecules, are characterized by their power of forming addition compounds with numerous chemical reagents. This characteristic distinguishes them from the paraffin hydrocarbons which are capable of forming substitution derivatives only, i.e., compounds in which one or more hydrogen atoms of the paraffin are replaced by other atoms or groups of atoms. The direct combination of the olefin hydrocarbons with halogens to yield, initially, dihalogen derivatives of the corresponding paraffin (or olefin dihalides), in which the two halogen atoms are attached to adjacent carbon atoms is an example of this power. The constitution of the olefin dihalides may be expressed in the general formula



where X is a halogen atom and R_1, R_2, R_3, and R_4 are hydrogen atoms or alkyl groups. It has been known for over a century that ethylene possessed this important property which has since been found to be a general reaction of the unsaturated hydrocarbons as a class. The reaction between monolefins and halogens is most vigorous in the case of bromine, chlorine comes second, and iodine reacts more slowly. It also appears to be a rule that the rate of halogenation of the simple monolefins increases with increasing molecular weight up to a maximum and then probably decreases, though constitutional influences play an important rôle.[1] In a few cases the combination of olefin with halogens is extremely slow because of steric hindrance. In actual practice, moreover, though the addition of halogens to olefins occurs rapidly, substitution also takes place to some extent with the production of polyhalogen compounds. This is especially true when the olefin contains reactive hydrogen atoms, readily replaceable.

The power of unsaturated hydrocarbons of directly combining with halogens is the basis of a number of important methods for estimating these hydrocarbons more especially in mixtures with other substances, e.g., in cracked gasoline. The halogens generally used for this purpose are bromine and iodine, the amount of halogen absorbed by the olefin being determined under standard conditions. The Hanus[2] method employs iodine while the McIlhiney[3] and Francis[4] methods are based on combination with bromine. The bromine is obtained by treating a bromide-bromate solution with dilute sulphuric acid. It is liberated slowly and absorbed by the olefin as fast as it is formed, thus avoiding substitution. Though these methods are excellent in their way, they all have certain disadvantages, among which may be mentioned the following:[5]

---

[1] See Ingold and Ingold, *J.C.S.*, 1931, 2354, on the influence of substituents on the additive reactivity of ethylene derivatives.

[2] *Z. Nahr.-Genussm.*, 1901, 4, 913; *Chem. Soc. Abs.*, 1902, 82 (2), 112. Ingold and Smith, *J.C.S.*, 1931, 2742; Ingold and Ramsden, *J.C.S.*, 1931, 2746.

[3] *J.A.C.S.*, 1899, 21, 1084.

[4] *Ind. Eng. Chem.*, 1926, 18, 821.

(1) Frequently the theoretical absorption is not attained.
(2) The absorption depends upon the concentration of the reactants, upon the particular olefins under examination, and upon the time of reaction.
(3) Substitution reactions are exceedingly difficult to eliminate entirely.

Although a vast amount of work has been carried out on the preparation and properties of olefin halides, the quantity of really fundamental research on the mechanism of the process is surprisingly small.

According to Plotnikov[6] the union of ethylene and bromine to form the dibromide occurs instantaneously and completely at ordinary temperatures and the reaction only slackens to a measurable velocity at —100° C., at which temperature the reaction (in petroleum ether solution) was found to be of the second order. Stewart and Edlund,[7] on the other hand, found the combination of bromine (mixed with air) and ethylene in the gaseous state was slow at 0° C. though approximately 10 times as fast as the vapor-phase combination of ethylene and chlorine mixed with dry air at 17° C. In both instances the reaction was considered as being mainly a surface phenomenon,[8] which took place principally on the walls of the container. A very thorough examination of the relative rates of bromination of the olefins, particularly in carbon tetrachloride solution, has been made by Davis,[9] whose work has helped to clarify our ideas in this field. This investigator found that the rate of combination of ethylene and bromine in carbon tetrachloride in the dark depended greatly upon the quantity of moisture present in solution. When the reagents were very carefully dried the dark reaction was very slow, the second order reaction coefficient K being as low as 0.006 at 25° C. Bright light enormously increased the rate of bromination in dry carbon tetrachloride, while, remarkable to relate, the rate of bromination increased progressively as the temperature was reduced from 25° to 0° C. The phenomenal increase in the rate of reaction with the decrease in temperature was attributed to the reaction proceeding through the agency of a bromine hydrate and not by direct combination of ethylene and bromine. This hypothesis also explained the importance of small amounts of moisture in this reaction. Just as with ethylene, the bromination of propylene (dark reaction) in dry carbon tetrachloride was considerably faster at 0° C. than at 25° C., though, on the other hand, temperature changes seemed to have little influence on the rates of bromination of trimethylethylene and di-isobutylene. Davis studied the rate of bromination (dark reaction) of various olefins in dry carbon tetrachloride at 25° C. In Table 99 are given the *lowest* values obtained for the velocity coefficient K; the relative values are to be regarded as only qualitative.

TABLE 99.—*Velocity Coefficient of Bromination of Various Olefins.*

Olefin	K	Olefin	K
Ethylene	0.006	Butene-2 Isobutene	60.0
Propylene	0.2	Trimethylethylene	250.0
Butene-1	2.0	Di-isobutene	20.0

---

[9] *J.A.C.S.*, 1928, **50**, 2769.

It will thus be seen that ethylene brominates at the slowest rate[10] while, of the olefins examined, trimethylethylene displayed the greatest reaction velocity. The reactivity of the simple monolefins thus appears to be at a maximum with the pentenes and their immediate homologues. A comparison of the rates of bromination of olefins in dry carbon tetrachloride in the dark and also when exposed to light showed that in the light the rates of reaction tend to show less divergency than in the dark. This interesting fact is brought out by the figures in Table 100, given by Davis, for the reaction coefficients, *K*, for ethylene, propylene, and di-isobutylene in the dark and the light, respectively.

TABLE 100.—*Velocity Coefficient of Bromination of Ethylene, Propylene and Di-isobutylene.*

	K Dark Reaction		*K* Light Reaction	
	Values	Ratios	Values	Ratios
Ethylene	0.01	1	2	1
Propylene	0.2	20	2.5	1.3
Di-isobutylene	20.0	2000	40.0	20.0

NOMENCLATURE OF HALOGENATED DERIVATIVES OF HYDROCARBONS

In the naming of addition products of unsaturated hydrocarbons some questions concerning their designation may arise. For example, dichloroethylene ($ClHC{=}CHCl$) may be easily confused with ethylene dichloride ($ClH_2C.CH_2Cl$). The former is an unsaturated compound, whereas the latter is completely saturated. In names such as "acetylene dichloride" the compound is less unsaturated than the hydrocarbon used for its designation. It does not contain an acetylene triple bond. The exact unsaturation of the compound is indicated more clearly by its other name, "dichloroethylene," which shows that it contains only a double bond. The naming of the halogenated compounds by means of the unsaturated hydrocarbon from which they are derived serves to emphasize their origin. Although to the chemist ethylene dichloride and 1,2-dichloroethane are the same material and both designations are equally acceptable, nevertheless, the name "ethylene dichloride" has been used to designate the compound made from ethylene by addition of chlorine, and "1,2-dichloroethane" to mean that made by substitution of chlorine for hydrogen atoms in ethane. Such distinctions are purely arbitrary, however. As the series of hydrocarbons is ascended and the structures of the derivatives become more complex, the halogen compounds can only be designated as derivatives of the hydrocarbon, preceded by a prefix indicating the nature and number of the halogen atoms.[10a] To avoid any confusion which may result Table 101 gives the known chlorinated products of the C_1 and C_2 hydrocarbons,[10b] from which the higher derivatives can be designated by analogy.

THE ETHYLENE DIHALIDES AND THEIR DERIVATIVES

Although ethylene reacts less rapidly with halogens than its immediate homologues, good yields of the dichloride and the dibromide may be readily obtained. These substances, especially the former, are assuming a position of some indus-

---

[10] This is in agreement with the results of Suida and Wesely (*Z. anal. Chem.*, 1924, 64, 147) who state that ethylene reacts the slowest of the simple olefins toward bromine water.

[10a] *Cf.* Patterson, "Definitive Report of the Commission on the Reform of the Nomenclature of Organic Chemistry," *J.A.C.S.*, 1933, 55, 3914; Bernthsen-Sudborough, "Textbook of Organic Chemistry," D. Van Nostrand Co., Inc., New York, 1922, 58.

[10b] Some of these derivatives are discussed in later chapters (28, 29, and 30).

TABLE 101.—*Chlorinated Products of the C_1 and C_2 Hydrocarbons.*

Formula	Chemical Names	Other Names	Physical Properties[a] M.P. °C.	B.P. °C.	$D^{20°}_{4°}$

trial importance. Iodine reacts slowly with ethylene in direct sunlight at about 60° C.,[11] but this reaction does not as yet appear of technical interest. The fluorine derivatives of the lower olefins have been little investigated and offer a very promising field of research.

ETHYLENE DICHLORIDE (1,2-DICHLOROETHANE)

Ethylene dichloride, $ClCH_2{\cdot}CH_2Cl$, is a heavy colorless liquid with a chloroform-like odor and having the following physical characteristics:—boiling point 83.5° C. at 760 mm.; freezing point —36° C.; d^{20}_4 1.2569; d^0_4 1.2824; n^{20} 1.444; viscosity at 25° C., 0.78 centipoises; vapor pressure at 20° C. 61.6 mm.; specific heat at 30° C. 0.3054 calories per gram; surface tension at 25° C., 37.5 dynes per sq. cm.; closed cup flash point, 58° F.; apparent ignition temperature in air, 499° C.; latent heat of evaporation at 82.2° C., 77.34 calories per gram.[12]

Ethylene dichloride is practically insoluble in water, sparingly soluble in alcohol and ether, and miscible with ethereal oils, fats, and mineral oils generally. It is one of the most stable of the commonly available chlorinated hydrocarbons and may be handled in the presence of water at its boiling point without danger of corrosion to metal apparatus. Besides its stability to hot water it is also resistant to oxidation. Although ethylene dichloride will burn, this substance is on the border line between inflammable and non-inflammable solvents and ethylene dichloride flames are readily extinguished. Its lower explosive limit in air is 6.2 per cent compared with 1.4 per cent for benzene and about 1.5 per cent for ordinary gasoline.[12] Exposure to light is said to promote decomposition and hydrolysis but the addition of 1 or 2 per cent of alcohol increases its stability.

Ethylene dichloride was first prepared about 1795 by four Dutch chemists, Delman, Bondt, van Troostwyk, and Lauwerenburgh,[13] by the action of chlorine on ethylene, hence this substance became known under the name of "Dutch Liquid." Since that time this compound has been the subject of a number of academic investigations but it was not available in quantity and at low price until about 1927. In order to prepare this material cheaply, an abundant and cheap supply of both chlorine and ethylene (the latter, for example, from vapor-phase cracking of petroleum) is essential.

The scientific work carried out on the chlorination of ethylene indicates that combination in the dry state and in the vapor phase at ordinary temperatures only occurs slowly.[14] The reaction may apparently be speeded up by working in the liquid phase, by the use of catalysts, by employing a solvent, or by using higher temperatures, but it is very difficult to limit the reaction to direct addition since substitution also occurs readily especially at higher temperatures. Doroganevskaja [15] has indicated that gaseous chlorine and ethylene do not combine in the absence of a catalyst. In glass vessels reaction takes place due to the catalytic effect of the glass itself, and the reaction can be further accelerated by the addition of ethylene dichloride. Under the proper conditions, such as concentration or velocity of the gases, yields of ethylene dichloride as high as 93.6 per cent can be obtained. Moreover, the addition reaction is highly exothermic and the heat liberated in this process, unless rapidly absorbed, tends to promote substitution reactions. Thus Smythe[16] found that ethylene and chlorine reacted very readily in the presence of calcium chloride as catalyst, so much heat being generated that the apparatus had to be cooled during the operation. The chlorinated product contained about 50 per cent of ethylene dichloride, 25 per cent of trichloroethane, and 25 per cent of higher-boiling products, probably polyhalogenated derivatives.

According to the observations of Stewart and Smith,[17] under certain circumstances the vapor-phase combination of chlorine with ethylene leads to a quantitative formation of ethylene dichloride while, under other conditions, only 1,2,2-trichloroethane and hydrogen chloride are formed. The substitution reaction is induced by the addition reaction, the heat of formation of ethylene dichloride being utilized to promote the formation of trichloroethane. In the absence of moisture and light the reactions are autocatalytic, while the presence of oxygen inhibits the utilization of the reaction energy to promote substitution, i.e., suppresses the substitution reaction. Nitrogen and moisture have little effect. Bahr and Zieler[18] have observed that, in the absence of catalysts, ethylene dichloride is formed from ethylene and chlorine in 90 per cent yield at —20° to —30° C. Lower temperatures do not increase the yield, while at higher temperatures the yield is decreased. Trichloroethane is formed in increasing amount with rising temperature and constitutes the main product at ordinary temperatures. The amount of tetrachloroethane formed, though always small, increases with rising temperature. According to Bahr and Zieler, the higher chlorinated products are not produced by subsequent action of chlorine on ethylene dichloride but by direct action of chlorine on ethylene. The course of the reaction was found to depend mainly on the temperature and not on the relative proportions of the reactants.

A number of processes dealing with the production of ethylene dichloride from ethylene and chlorine have been developed; in many of these, however, it is possible that the products are contaminated to some extent by higher chlorinated substances.

Tinker[19] made olefin dichlorides by passing cracking gas, chlorine, and a cold inert liquid (e.g., ethylene dichloride) through a reaction tower. The products pass to a condenser which removes the olefin dihalides, leaving a gas consisting mainly of paraffins. Vapor-phase chlorination of gaseous olefins to produce olefin dichlorides at 50° to 150° C. in the absence of steam or water and in the presence of contact substances such as brick, pumice, sand, coke, charcoal, ferric oxide, alumina, or magnesia is suggested by Harding.[20] The products are said to be practically free from higher substitution compounds. Bergius[21] described the use of coal gas, or the gaseous products obtained from the distillation of carbonaceous matter (lignite or oils), as a source of ethylene for the manufacture of ethylene dichloride by vapor-phase catalytic chlorination, followed by compression and cooling to separate the ethylene dichloride. Chlorination is said to take place in the presence of porous charcoal, with or without the addition of a halogen carrier, such as chlorides of antimony, sulphur, or phosphorus.[22]

[22] Farbenfabriken vorm. F. Bayer and Co., British Patent 177,362, 1921; *Chem. Abs.*, 1922, 16, 3093.

It is stated that natural magnesite, which has been heated for some time at 400° to 500° C., is a catalyst for chlorination reactions, particularly the chlorination of ethylene to the dichloride.[23]

In the process developed by the T. Goldschmidt A.-G.[24] a mixture of ethylene and chlorine, with the ethylene in excess, is passed over catalysts at temperatures of 30° to 120° C. in such a manner that the ethylene dichloride formed is rapidly removed from the reaction zone. Askenasy and Heller[25] have recommended that the reaction between ethylene and chlorine take place in the presence of lead, as a catalyst, and that the temperature of the reaction zone be kept below 100° C.

Among the more interesting processes are those of Curme[26] who described the production of ethylene dichloride by mixing dry ethylene with liquid chlorine at a temperature below 0° C. and at a pressure corresponding to the vapor pressure of chlorine. At higher temperatures higher chlorinated substances are said to be formed. It is understood that the process, which appears to be equally simple and efficient, is one which has been employed for large-scale production of ethylene dichloride. According to Maier[27] ethylene dichloride is produced by bringing together ethylene and chlorine, both of which have been previously cooled to a low temperature, for example —30° C. The reaction velocity between gaseous ethylene and liquid chlorine (at —78° C.) is almost proportional to the partial pressure of the ethylene.[28] Backhaus[29] described a process for preparing pure dihalide by passing a mixture of an olefin and a halogen, e.g., chlorine and ethylene, in a continuous stream through cooled tubes while continuously returning the uncombined gases to the stream entering the tubes.[30]

A two-stage process for making ethylene dichloride consists in first allowing ethylene to react with an insufficient amount of chlorine (both in the gaseous phase) for complete reaction and second completing the chlorination by the use of a saturated solution of chlorine in liquid chlorohydrocarbons.[31]

Ernst and Wahl[32] utilized chlorine produced *in situ* by the oxidation of hydrogen chloride. The process, which is a continuous one, may be summarized in the equation:

$$2C_2H_4 + 4HCl + O_2 = 2C_2H_4Cl_2 + 2H_2O$$

For example, a mixture of 100 volumes of air, about 20 volumes of ethylene and at least 40 volumes of hydrogen chloride is passed through an acid-resisting contact chamber containing lumps of pumice soaked with cupric chloride and maintained at 300° C. Besides ethylene dichloride, only traces of other chlorinated hydrocarbons are formed. The use of active charcoal, saturated with sulphur chloride, as a catalyst for the combination of ethylene and chlorine to yield ethylene dichloride has been proposed by Wietzel and Dierksen.[33]

Mersereau[34] has described a method of treating olefins, or diolefins, with chlorine in a (dark) tower down which a shower of cooled water or chlorinated hydrocarbons is allowed to flow. When pure chlorine is used and water is employed to control the temperature, the most desirable reaction temperature is 15° C. The apparatus suggested by Mersereau consisted essentially of a vertical reaction tower, the lower end of which is placed in a container employed to collect the water and the chlorinated products. Both chlorine and ethylene are introduced at the bottom of the tower through perforated openings to secure good mixing, and reaction takes place as the gaseous mixture travels upwards. Cold water is sprayed into the top of the tower. Water and chlorinated products are retained in the container at the bottom of the tower, and because of their wide differences in densities readily separate into two layers which can be withdrawn separately. The gaseous products leave the top of the reaction tower through a condenser. Any condensate formed is allowed to flow from the bottom of the condenser to the container at the bottom of the reaction tower.

Strosacker[35] has pointed out that the dichloride of ethylene, or of other olefins, may be obtained by passing the olefin, in the gaseous state, through a spray of antimony pentachloride dissolved in ethylene dichloride. Only addition compounds are said to be formed, no substitution reactions taking place. The chlorination of ethylene in an atmosphere consisting of the vapors of halogenated hydrocarbons containing a halogen of higher atomic weight than chlorine, as for example ethylene dibromide, has been described by Dow.[36]

Summarizing, it may be said that in order to obtain pure ethylene dichloride by the chlorination of ethylene and fairly free from substitution derivatives, it is necessary to maintain the reaction mixture at a fairly low temperature. Among the best methods of carrying out this reaction on an industrial scale is by passing cooled ethylene into cooled liquid chlorine at a low temperature in the absence of catalysts.

When ethylene is treated with dilute hypochlorous acid, ethylene chlorohydrin is produced almost exclusively, but in the case of the higher homologues of ethylene considerable amounts of olefin dichloride are simultaneously formed with the chlorohydrin.

OTHER METHODS FOR THE PRODUCTION OF ETHYLENE DIHALIDES

Ethylene dihalides may be produced, according to Bauer,[37] by the direct addition of two molecules of hydrogen halide to acetylene at ordinary temperatures in the presence of a gaseous oxidizing agent such as air, oxygen, nitrogen, peroxide, formaldehyde, formic acid or iodine. The corresponding dihalide is said to be rapidly formed in a yield of 90 per cent. The reaction may be represented thus:

$$CH\equiv CH + 2HX \longrightarrow CH_2XCH_2X$$

Although on the basis of former work the opinion has been expressed[38] that the addition of two molecules of halogen acid to acetylene leads to the production of the 1,1-dihalogenoethane exclusively, other work[39] has shown that both the 1,1- and the 1,2-ethylene dihalides are produced. Wibaut[40] has very thoroughly examined this reaction in the case of hydrogen bromide and acetylene and found that, though a mixture of the two dibromoethanes was produced, reasonably good yields of ethylene dibromide (1,2-dibromoethane) could be obtained using certain metallic chlorides on asbestos as catalysts. Evidently, therefore, the direct addition of hydrogen chloride to acetylene to yield ethylene dichloride is entirely possible, provided the correct conditions can be found.

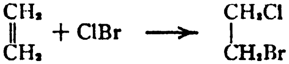
[38] Meyer-Jacobson, "Lehrbuch der organischen Chemie," 1913, II, 27.

It has also been reported that ethylene dichloride[41] may be produced by the direct chlorination of ethane in the presence of activated carbon and over a temperature range from 100° to 300° C. At the same time, however, ethylidene chloride (in quantities equivalent to the ethylene dichloride) and some 1,1,1-trichloroethane are formed.

In this connection it is interesting to note that when ethylene is allowed to react with an equimolecular mixture of chlorine and bromine (presumably the compound ClBr), 1-chloro-2-bromoethane is the main product in the cold.[42]



$$\begin{matrix} CH_2 \\ \| \\ CH_2 \end{matrix} + ClBr \longrightarrow \begin{matrix} CH_2Cl \\ | \\ CH_2Br \end{matrix}$$

According to Dow,[43] when ethylene is allowed to react with a gaseous mixture of equal atomic proportions of chlorine and bromine (obtained by bubbling chlorine through liquid bromine at 15° to 20° C.), 1-chloro-2-bromoethane is readily formed.

Uses of Ethylene Dichloride

Ethylene dichloride is a substance which can be produced in large quantities, and will probably find a number of varied applications. Already it has been suggested as a solvent, as a fumigant, as an ingredient in the manufacture of lacquers and especially in the synthesis of ethylene glycol or its derivatives.

As a solvent ethylene dichloride possesses many desirable characteristics, as for example its low cost, high solvent power, low inflammability, and availability in large quantities.[44] It is an excellent solvent for many fats, oils and resins, but will not dissolve cellulose nitrate or acetate except after being mixed with certain other solvents. A mixture containing 70 to 80 per cent of ethylene dichloride and 20 to 30 per cent of methyl or ethyl alcohol is said to possess a high solvent power for cellulose acetate.[45] Other proposed uses which involve its solvent powers are as an extracting agent in the manufacture of vegetable oils; in the separation of mineral oils from paraffin wax,[46] the latter substance being only slightly soluble in this solvent at temperatures below 25° C.; as a dry cleaning agent, either alone[47] or admixed with other chlorinated hydrocarbons, such as carbon tetrachloride or propylene dichloride.[48] Ethylene dichloride is cheaper than carbon tetrachloride on a volumetric basis and superior in its stability toward water and steam.[49]

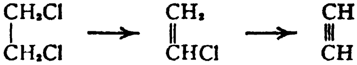
Frazier and Reid[50] have discussed the use of ethylene dichloride in the manufacture of lacquers. Its advantages appear to be resistance to hydrolysis in the presence of water and low inflammability. Its disadvantage is the fairly high rate of evaporation which necessitates the addition of a higher-boiling solvent as a "leveller".

When employed as a fumigant it is often mixed with carbon tetrachloride to render it non-inflammable, approximately 25 per cent by volume of carbon tetrachloride being sufficient. A number of tests with a 3:1 mixture of ethylene dichloride and carbon tetrachloride on grain, flour, food and seeds has been recorded by Hoyt.[51] According to Russ[52] both ethylene dichloride and ethylene oxide are highly toxic to insects but relatively non-toxic to man.

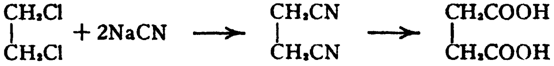
The conversion of ethylene dichloride to ethylene glycol, by hydrolysis with aqueous sodium carbonate, or to glycol diacetate, by heating with an anhydrous salt of acetic acid, is discussed in Chapter 22. When heated with caustic alkalies ethylene dichloride loses first one molecule of hydrogen chloride to yield vinyl chloride. The properties and uses of this latter compound are mentioned in Chapter 28. Further treatment with caustic alkalies eventually yields acetylene, thus:



$$\begin{array}{c}\mathrm{CH_2Cl}\\ |\\ \mathrm{CH_2Cl}\end{array} \longrightarrow \begin{array}{c}\mathrm{CH_2}\\ \|\\ \mathrm{CHCl}\end{array} \longrightarrow \begin{array}{c}\mathrm{CH}\\ |||\\ \mathrm{CH}\end{array}$$

A similar series of changes occurs when ethylene dichloride is subjected to pyrolysis at 600° C. in an atmosphere of nitrogen, vinyl chloride and hydrogen chloride being produced[53] (this reaction is probably reversible at lower temperatures), while at still higher temperatures acetylene is produced.

Ethylene dichloride may also be employed for the manufacture of succinic acid. Condensation with sodium cyanide produces succinonitrile, which may be readily hydrolyzed by means of hydrochloric acid to yield succinic acid, thus:



$$\begin{array}{l}\mathrm{CH_2Cl}\\ |\\ \mathrm{CH_2Cl}\end{array} + 2\mathrm{NaCN} \longrightarrow \begin{array}{l}\mathrm{CH_2CN}\\ |\\ \mathrm{CH_2CN}\end{array} \longrightarrow \begin{array}{l}\mathrm{CH_2COOH}\\ |\\ \mathrm{CH_2COOH}\end{array}$$

The condensation of ethylene dichloride and sodium cyanide is very conveniently effected by heating in the presence of succinonitrile itself.[54] This replacement of the chlorine atoms in ethylene dichloride by other groups may be accomplished occasionally in a single step. For example, in making ethylene dithiocyanate, sodium thiocyanate in the dissolved form and chlorine are allowed to react with ethylene.[55] This reaction is said to be applicable also to the homologues of ethylene.

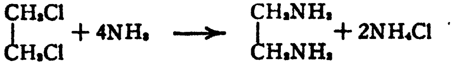
[55] Kauffmann, U. S. Patent 1,859,399, May 24, 1932; assigned to I. G. Farbenindustrie A.-G.; *Chem. Abs.*, 1932, 26, 3804.

Ethylenediamine may be produced from ethylene dichloride by interaction with ammonia according to the equation



$$\begin{matrix} CH_2Cl \\ | \\ CH_2Cl \end{matrix} + 4NH_3 \longrightarrow \begin{matrix} CH_2NH_2 \\ | \\ CH_2NH_2 \end{matrix} + 2NH_4Cl$$

Thus on heating ethylene dichloride with 33 per cent aqueous ammonia for 5 hours in an autoclave at 115° to 120° C., a good yield of ethylenediamine is obtained.[56] Ethylenediamine is an oily base of melting point 8.5° C., boiling point 116.5° C. at 760 mm. and d^{15}_{4} 0.902.

The reaction between ethylene dichloride and ammonia at high temperatures and under pressure can be made to yield polyethylene polyamines which have been recommended as rubber vulcanization accelerators.[57] It is stated that this procedure effects both condensation and polymerization.

Chloroethylsulphuryl chloride can be prepared by treating ethylene dichloride with fuming sulphuric acid (60 to 65 per cent SO_3) in the cold. On diluting with water the chloroethylsulphuryl chloride separates as a colorless heavy oil with an odor like that of formaldehyde and a boiling point of 120° to 122° C. at 80 mm. The yield is good but not quantitative since a certain amount of dichlorethyl sulphate, a colorless oil, boiling point 180° to 182° C. at 60 mm., is also formed.[58]

Ethylene dichloride reacts with metal sulphites in ethyl or methyl alcohol to yield salts of chloroethanesulphonic acid,[58a] from which the acid chloride may be obtained. Catalysts for the reaction are copper, copper sulphate, and barium chloride.

The production of plastic materials by the interaction of ethylene dichloride and the polysulphides of alkali or alkaline earth metals has been described by Patrick and Mnookin.[59] These products resemble soft rubber, and are characterized by a high sulphur content and insolubility in organic solvents except carbon disulphide. They also possess vulcanizing properties, and can be incorporated with unvulcanized rubber and the mixture subjected to vulcanization.

The plastic materials, being rubber-like, may be compounded and vulcanized like rubber itself. The product so obtained is insoluble in organic solvents, particularly petroleum distillates, and can be used, for example in the form of hose, for the handling of these solvents. Another use is in electrical insulation.

Baer[60] also has made plastic materials by the reaction between chlorinated hydrocarbons, such as ethylene dichloride, and the alkali or alkaline earth sulphides. Such materials are capable of being milled, compounded, molded or vulcanized like rubber itself. Another method of producing rubber-like substances is by the interaction of the chlorinated derivatives of unsaturated hydrocarbons, such as isoprene, and alkali and alkaline earth sulphides.[61]

The preparation of factice or sulphuretted oil products, which are soluble in hydrocarbons, by heating equal weights of a vegetable oil, e.g., rape seed oil, and a caoutchouc-like body, made from ethylene dichloride and alkali polysulphides, has been described by Baer.[62] The same rubber-like products can also be dissolved in carbon disulphide and mixed with rubber latex.[62a]

Some other uses which have been proposed for ethylene dichloride are: (a) as one of the components of a solvent for the polymerization of butadiene by means of sodium[63]; (b) for the production of cellulose ethers or as one of the components of mixed solvent for such ethers[64]; (c) together with isopropyl ether, acetone, propylene dichloride and chlorinated naphthalene as a composition for the removal of carbon in internal-combustion engines.[65]

TRICHLORO- AND TETRACHLOROETHANE

Two general types of reactions can be used in the preparation of these compounds as well as higher chlorinated derivatives. These reactions may be classified as (a) the further chlorination of lower chlorinated derivatives, or (b) the action of chlorine on unsaturated hydrocarbons, particularly acetylene, as in the case of tetrachloroethane.[66]

1,1,2-Trichloroethane, for example, can be prepared by the reaction between chlorine gas and ethylene dichloride at a temperature of about 60° C. and in the presence of such catalysts as antimony, iron or manganese.[67] This same compound may be obtained by allowing chlorine and ethylene to react at 30° C. and using a metal, such as copper, as a catalyst.[68] Vinyl chloride and chlorine are said to yield 1,1,2-trichloroethane when allowed to react at temperatures of 100° C. to 250° C. in the absence of a solvent and of light.[69]

Other methods for producing both 1,1,2-trichloro- and 1,1,2,2-tetrachloroethane involve the reaction between acetylene and either chlorine or a mixture of chlorine and hydrogen chloride. A discussion of these will be found in Chapter 28.

1,1,2-Trichloroethane is a colorless liquid boiling at 114° C. and having d^0_0 1.4784. It is practically insoluble in water, but miscible in all proportions with alcohol or

ether. 1,1,2,2-Tetrachloroethane is a colorless liquid possessing an odor much like that of chloroform. It boils at 147° C. and has d_0^0 1.614. Its miscibility with other liquids is similar to that of 1,1,2-trichloroethane.

These two liquids appear to be somewhat less stable than ethylene dichloride. In the presence of moisture they are stable in contact with either tin or lead; other metals, however, slowly reduce them, under the same conditions, to the respective ethylene derivatives containing one less chlorine atom. Their uses are similar to those of ethylene dichloride as they are solvents, either alone or mixed with other liquids, for many substances such as fats, oils, waxes, cellulose esters or resins. As an example, in the preparation of an insecticide either chrysanthemum or derris root is extracted with a mixture containing 67.6 per cent trichloroethane and 32.4 per cent methyl alcohol. Evaporation of the solvent leaves a residue which may be used in the production of insecticides.[70] Tetrachloroethane has been suggested also as a component of soap compositions.[71]

HEXACHLOROETHANE

Mention should be made of a substance which may be readily obtained by chlorinating ethylene with an excess of chlorine, namely hexachloroethane, C_2Cl_6. Miller[72] found this substance could be readily produced by passing ethylene mixed with a slight excess of chlorine through a pyrex tube packed with activated charcoal at 300° to 350° C. A 10 per cent excess of chlorine over and above that required for the reaction, $C_2H_4 + 5Cl_2 \rightarrow C_2Cl_6 + 4HCl$, suppresses the formation of lower chlorinated products and with a flow of 60 cc. of ethylene per minute over 200 grams of charcoal a conversion of 80 to 90 per cent of the theoretical was obtained.

Hexachloroethane may be prepared also by passing acetylene into a boiling mixture of sulphur chloride. The yield may then be further increased by leading alternate streams of chlorine gas and acetylene into this mixture.[73] Tetrachloroethane may be converted to hexachloroethane very rapidly and almost quantitatively by the action of chlorine in the presence of light from either an open arc lamp or a mercury vapor lamp. Pentachloroethane may be obtained as an intermediate product if the reaction is stopped when about 10 per cent excess chlorine (over that required for the pentachloride) has been added.[74]

ETHYLENE DIBROMIDE (1,2-DIBROMOETHANE)

Ethylene dibromide may be readily prepared[75] by passing ethylene through cooled bromine or bromine and water, the latter being often added to prevent evaporation of the bromine. Its preparation is described by Kesting[76] as follows: The ethylene, prepared by conducting ethyl alcohol vapors over clay or aluminum oxide at 250° to 400° C., is passed into cold liquid bromine. The reaction, which is accelerated by sunlight, proceeds smoothly and the crude ethylene dibromide, after being washed with water, caustic soda, again with water, and dried with calcium chloride, is fractionated.[76a] About 95 per cent yields of ethylene dibromide are obtained.

The thermal combination of ethylene and bromine at glass surfaces has been studied very thoroughly by Williams.[77] The rate of reaction, under a variety of pressures, temperature and surface conditions, was determined by measuring the change in pressure of a mixture of ethylene and bromine vapor. Precautions were taken to exclude light as the reaction is slightly photosensitive.

At room temperature combination was found to be a surface reaction, which is in agreement with the results obtained by other investigators at 0° C. Furthermore the reaction appeared to be a simple addition of bromine to the double bond, unless the bromine was present initially in excess when an undetermined supplementary reaction took place.

The rate of reaction decreased with rise in temperature and the order of reaction was found to be either second, first, or zero (in one instance) depending on the glass surface. For a given glass surface, either lowering the temperature or increasing the pressure of the reactants lowered the order of the reaction. For a given glass surface and reaction order, the magnitude of the velocity coefficient was independent of the initial ethylene pressure; it did increase, however, with increasing initial bromine pressure.

The presence of water vapor was found to accelerate the reaction, while baking the glass containers before use removed this influence. A glass surface which exhibits a second order reaction when dry shows a first order reaction in the presence of water vapor. This seems to indicate that bromine is hydrated at the surface of the glass, and that the ethylene reacts with the bromine hydrate.

This transition from a second order to a first order reaction was observed also when the surface concentration of the bromine hydrate was so high that the chance of collision between a molecule of ethylene and a molecule of bromine hydrate was independent of the gaseous bromine pressure.

The rate of reaction was increased by the initial introduction of ethylene dibromide vapor and also there were some indications that reaction chains may start at the surface of the glass and then spread into the gas phase.

Williams[77a] showed that the reaction between ethylene and bromine in carbon tetrachloride was autocatalytic. Though Davis[77b] suggested that water may be a catalyst, this is not believed by Williams. Hydrobromic acid was found to increase the reaction velocity appreciably.

Ethylene dibromide may also be prepared by the catalytic combination of hydrogen bromide with either acetylene or vinyl bromide. According to Bauer,[78] the production of ethylene dibromide by the combination of two molecules of gaseous hydrogen bromide and acetylene proceeds quantitatively under the influence of strong sunlight or light from a quartz lamp; the same reaction can be carried out also in the vapor phase in the presence of oxidizing gases, such as air, oxygen, nitrogen peroxide, and ozone.[79] Reboul[80] made the remarkable discovery, to some extent substantiated by Wibaut, that when vinyl bromide is treated with very concentrated aqueous hydrobromic acid 1,2-dibromoethane is formed but with less concentrated acid 1,1-dibromoethane is formed. Wibaut[81] has shown that the direct combination of gaseous hydrogen bromide with vinyl bromide at 100° C. in the presence of glass wool and asbestos as catalysts produces mainly 1,2-dibromoethane; but silica gel and bismuth bromide and ferric bromide—if used without a support—direct the reaction to the formation of the 1,1-isomer. It was also shown that 1,2-dibromoethane can be obtained in reasonable yields from acetylene and gaseous hydrogen bromide in the presence of ferric bromide or mercuric bromide on asbestos at 100° C. The addition of hydrogen bromide to vinyl bromide in solutions of hydrobromic acid was found to lead to the formation of 1,1-dibromoethane exclusively when acid of specific gravity 1.60 was used, although with stronger acid (of specific gravity 1.86) a mixture of isomers containing about 35 per cent of the 1,2-isomer was formed. In glacial acetic acid solution, 1,1-dibromoethane was always the main product of the reaction.

[76a] Heath and Keller (U. S. Patent 1,921,157, Aug. 8, 1933; assigned to Dow Chemical Co.; *Chem. Abs.*, 1933, 27, 5086) purified ethylene dibromide by steam distillation and fractionation.

Ethylene dibromide is a colorless, sweet-smelling liquid of melting point 10.0° C., boiling point 131.6° C. at 760 mm., and d^{20}_{4} 2.1816. It burns only with difficulty.

Ethylene dibromide has been used considerably in the past for various organic syntheses but it will probably be replaced for this purpose by the cheaper dichloride. The greatest application of the compound nowadays is in a mixture with tetraethyl lead as an anti-knock agent in motor fuels.[82] The lead is eliminated from the engine, after the explosion, in the form of its dibromide, the bromine being derived from ethylene dibromide. It is reported[83] that about 300,000 pounds of ethylene dibromide per month were exported in 1930 from Germany to the United States for use in connection with the production of anti-knocking agents. This bromide is probably made from ethylene extracted from coke-oven gas.

It is interesting to note that ethylene dibromide and olefin dibromides generally may be quantitatively reduced to the parent olefin by the aid of the zinc-copper couple of Gladstone and Tribe.[83a] This process is useful in the preparation and purification of olefins and has also been employed with success in the quantitative examination of olefin mixtures.[84] In some instances hydrogen in the presence of colloidal palladium will remove halogens from olefin halides without saturating the unsaturated linkages.[85]

ETHYLENE DI-IODIDE

Only brief mention need be made of this substance as it has not yet been used industrially to any large extent. In the laboratory, however, it is often used in the synthesis of organic compounds.

The reaction between iodine and ethylene to yield ethylene di-iodide has long been known. Semenow[86] observed the formation of this iodide when ethylene was passed into a paste of iodine and absolute alcohol; Faraday[87] reported its formation from iodine and ethylene in the presence of sunlight, while Regnault[88] showed the reaction took place in the dark when the reactants were warmed.

[88] *Ann.*, 1835, **15**, 67.

The reaction between ethylene and iodine appears to differ from those between ethylene and chlorine or bromine since it is reversible under ordinary conditions, and at equilibrium appreciable quantities of both ethylene and iodine are found. This equilibrium has been investigated by Mooney and Ludlam,[89] who were interested in the reaction in the gaseous phase and over a temperature range of 11° to 65° C. The same reaction has been studied in carbon tetrachloride solutions at temperatures varying from 120° to 150° C. by Polissar.[90]

Mooney and Reid[91] have pointed out that at 30° C. combination between iodine and ethylene is a surface reaction taking place almost entirely on the surface of the solid iodine. Glass surfaces were found to be unimportant as catalysts, and the rate of the reaction was found to be proportional to the square of the pressure of the ethylene.

Ethylene also reacts with cyanogen iodide to yield ethylene di-iodide; analogous reactions do not take place between cyanogen chloride or bromide and this olefin. The reaction was considered to take place in two steps: first the dissociation of cyanogen iodide into cyanogen and iodine, followed by the reaction of the iodine formed with the ethylene. This can be represented by the following equations:

$$2CNI \rightleftharpoons (CN)_2 + I_2$$

$$C_2H_4 + I_2 \longrightarrow CH_2ICH_2I$$

Ethylene di-iodide is a crystalline solid, melting at 81°-82° C., and having a specific gravity of 2.07. It is soluble in alcohol, and only slightly soluble in water.

Propylene Dichloride (1,2-Dichloropropane)

As already indicated, the addition of halogens to propylene proceeds much more rapidly than in the case of ethylene. In the chlorination of propylene it is very difficult to prevent simultaneous substitution reactions which result in the formation of some higher chlorinated products. For example, Goudet and Schenker,[92] by passing an equimolecular mixture of propylene and chlorine slowly through a cooled illuminated tube, and immediately washing the product with sodium carbonate solution, obtained an 80 per cent yield of propylene dichloride, together with small amounts of 1,2,2-trichloro- and 1,1,2,2-tetrachloro-propanes.

Propylene dichloride may be prepared also by the action of liquid chlorine on gaseous or liquid propylene, particularly in the presence of an inert solvent such as carbon tetrachloride or of propylene dichloride itself. Using an excess of liquid propylene, the product is pure dichloride, but if an excess of chlorine is employed the dichloride is obtained mixed with trichloropropane, and other higher chlorinated propanes.[93]

Propylene dichloride is a colorless liquid of boiling point 96.8° C. at 760 mm., d^{14}_{4} 1.66, n^{20}_{D} 1.4388, and possessing chemical and physical properties very similar to those of ethylene dichloride. It has been prepared in comparatively large quantities and will probably find important applications in chemical industries, possibly as a solvent or as a raw material for chemical synthesis. For example, it may be condensed with ammonia to give a diamine; or with sodium cyanide to yield a dinitrile, hydrolyzable to a methylsuccinic acid; or the dichloride may be hydrolyzed with aqueous sodium carbonate to give propylene glycol. It has also been suggested for the dehydration of acetic and other aliphatic acids.[93a] On treatment with alcoholic potassium hydroxide it gives a mixture (yield 95 per cent) of two isomeric chloropropylenes.

Fractional distillation of this mixture of isomers yields 25 to 30 per cent of the 2-isomer ($n^{6.5}_D$ 1.404) the remainder being a mixture of constant boiling point (boiling point 30° to 32° C.) consisting mainly of the 1-isomer.[94] Although the elimination of hydrogen chloride, either catalytically or under the influence of alkalies, from propylene dichloride does not normally yield allyl chloride, a mixture of chloropropylenes being usually obtained, the production of allyl chloride from propylene by passing this substance in the vapor state over a calcium chloride catalyst at 300° to 350° C. has been described by Essex and Ward.[95] Similarly allyl bromide is said to be formed from propylene dibromide, the reaction being represented as follows:

$$CH_3CHXCH_2X \longrightarrow CH_2{=}CHCH_2X + HX$$

$CH_3CHClCH_2Br$ was prepared by Friedel and Silva[96] by boiling propylene dibromide with mercuric chloride under a reflux apparatus. It is a limpid, colorless liquid of boiling point 120° C., d^0_4 1.585 and d^{16}_4 1.475, which has been used in chemical synthesis.

PROPYLENE DIBROMIDE (1,2-DIBROMOPROPANE)

This substance can be readily prepared by passing propylene into cooled bromine or bromine water.[97] It was obtained by Prunier[98] by passing the gaseous products of pyrolysis (at a "red" heat) of light petroleum oils, through a series of bottles containing bromine. Armstrong and Miller,[99] in their classical researches on the products of bromination of "oil gas", isolated propylene dibromide as well as ethylene dibromide and butadiene tetrabromide.

Propylene dibromide may also be obtained, often mixed with 1,3-dibromopropane, by the direct combination of hydrogen bromide and allyl bromide. The composition of the product depends to a large extent upon the conditions[100] but propylene dibromide is formed almost exclusively when allyl bromide is allowed to react with anhydrous hydrogen bromide in glacial acetic acid solution at 100°

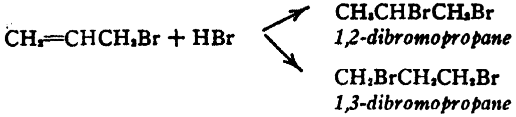
C. in the dark or when allyl bromide is heated in the dark at 100° C. with only moderately concentrated hydrobromic acid.[101] The use of hydrobromic acid of specific gravity 1.650 leads mainly to the formation of the 1,2-dibromopropane (propylene dibromide) while more concentrated acid favors the production of the 1,3-isomer. The reactions may be written:



$$CH_2{=}CHCH_2Br + HBr \begin{cases} \nearrow CH_3CHBrCH_2Br \ \textit{1,2-dibromopropane} \\ \searrow CH_2BrCH_2CH_2Br \ \textit{1,3-dibromopropane} \end{cases}$$

Propylene dibromide is a colorless heavy liquid of boiling point 141.6° C. at 760 mm.,[102] melting point —55° C.[103] and d^{20}_{4} 1.9333.[102] So far as is known, it has never been produced on a large scale for industrial purposes. Its possible applications are as a solvent and raw material for organic synthesis.

On treatment with alcoholic potash, propylene dibromide gives rise to a mixture of two isomeric bromopropylenes and on continued treatment a mixture of methylacetylene and allene is produced.[104] Various halogenated propylenes have been described but they have not yet achieved industrial importance.[105]

It has been shown by Favorsky and Sokovnin[106] that propylene dibromide, when subjected to pyrolysis, undergoes transformation into its various isomers, probably by elimination and addition of hydrogen bromide.

It is interesting to note that propylene di-iodide may be prepared by treating allyl iodide, cooled to —18° C., with a current of dry hydrogen iodide,[107] the reaction being analogous to that of the bromide previously discussed.

THE DIHALIDES OF THE BUTENES

The action of chlorine on butene-1 and butene-2 leads to the production of the dichlorides of these two olefins in the normal way. The chlorination of a mixture of isomeric butenes, produced by the catalytic dehydration of n-butanol over alumina at 480° C. has been described by Briner, Hausser and de Luserna.[108] The reaction between chlorine and this butene mixture was inexplosive in character (the heat of reaction, $C_4H_8 + 2Cl \rightarrow C_4H_8Cl_2$ vapor, being 33.4 cal.); and the combination was best effected by a carefully regulated mixing of the reactants in a cooled tube. The properties of the dichlorobutane, so produced, were: boiling point 114.6°-114.8° C. at 760 mm.; freezing point, indefinite; n^{20}_{D} 1.4325; d^{0}_{4} 1.44; $d^{99.5}_{4}$ 1.032; flame point, 62° C. According to Briner and his collaborators, this dichlorobutane, in solvent power for oils and fats, is equal to carbon disulphide and ethylene dichloride.

The dihalides of butene-1 can exist in optically active forms while the dihalides of butene-2 contain two asymmetric carbon atoms in their molecule and are therefore capable of existing in four stereoisomeric forms, a *dl, d, l,* and *meso* (internally compensated). The *dl*-butene-1 dichloride boils at 124° C. and

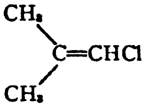
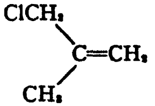
dl-butene-2 dichloride at 119° to 120° C.[109] On treatment with alkalies they both yield chlorobutenes.

The chlorination of isobutylene illustrates a rather general rule which was enunciated by Kondakoff[110] from a study of the chlorination of the amylenes, that olefins which combine very readily with mineral acids yield monochloro-olefins while those which do not readily combine with mineral acids give rise to the normal addition products on treatment with chlorine. In the case of isobutylene, Chechoukoff[111] found that treatment with chlorine resulted in the formation, not of the expected isobutylene dichloride, but of two isomeric chlorobutenes having the configurations:



$(CH_3)_2C{=}CHCl$

and



$(ClCH_2)(CH_3)C{=}CH_2$

The isobutylene dichloride, initially formed in this reaction, undergoes immediate decomposition with elimination of hydrogen chloride to yield chlorobutenes.

The bromine derivatives of the butylenes have been the subject of a number of important studies. Butene-1 dibromide, which is capable of optical activity, was prepared by Wurtz[112] by passing butene-1 into cooled bromine. It was similarly isolated by Lépingle,[113] together with other isomeric dibromides, by passing the gas produced by decomposing n-butanol (in the presence of alumina) into bromine. According to Lépingle it has the following physical properties: boiling point 166.3° C. at 760 mm., 50.8° C. at 13 mm. and d^{15}_4 1.8021. It solidifies at —65.4° C.[114] On treatment with alkalies it gives rise to a mixture of monobromobutenes[115] having the following formulas and physical properties:

(1) $CH_3CH_2CBr{=}CH_2$	b.p. 81.0° C. at 760 mm. m.p. —133.4° C. d^{15}_4 1.3209
(2) *cis*-$CH_3CH_2CH{=}CHBr$	b.p. 86.2° C. at 760 mm. d^{15}_4 1.3265
(3) *trans*-$CH_3CH_2CH{=}CHBr$	b.p. 94.7° C. at 760 mm. m.p. —100.3° C. d^{15}_4 1.3275

Butene-2 dibromide, existing in several stereoisomeric forms, was first produced by Wurtz.[116] Lépingle isolated two forms of this dibromide from the products of bromination of the gases resulting from the dehydration of n-butanol and assigned the following formulas to those compounds:

Meso-$CH_3CHBrCHBrCH_3$	b.p. 157.3° C. at 760 mm. b.p. 51.4° C. at 19 mm. m.p. —34.5° C. d^{16}_4 1.7913
dl-$CH_3CHBrCHBrCH_3$	b.p. 160.5° C. at 760 mm. b.p. 51–2° C. at 16 mm. d^{15}_4 1.7891

[116] *Ann.*, 1867, **144**, 236.

Later Young, Dillon and Lucas[117] obtained the stereoisomeric forms of butene-2 in a pure condition. On brominating the *cis*-isomer at 0° C., a dibromide of boiling point 75.6° to 75.8° C. at 50.0 mm., tentatively assumed to be the racemic compound, was obtained while the *trans*-hydrocarbon yielded a dibromide of boiling point 72.7° to 72.9° C. at 50 mm., which was probably the *meso*-isomer.

The halogenation of butane is said to be aided by simultaneously halogenating in the presence of 10 per cent by volume of butylene. The reaction is carried out in the dark at 0° to 30° C.[117a] On the other hand, when a mixture of butane and butylene is chlorinated in the presence of oxygen, the substitution reaction is stated to be suppressed.[117b]

On treatment with alcoholic potassium hydroxide, butene-2 dibromide was found by Hölz[118] to yield a monobromobutene, boiling point 87° to 88° C. at 760 mm., and having the structure $CH_3CBr{=}CHCH_3$. When this substance was treated with sodium ethoxide at 130° C. it was slowly converted into crotonylene, a further molecule of hydrogen bromide being eliminated. This reaction is typical of the olefin dihalides as a class.

Isobutylene dibromide, unlike the dichloride, may be obtained by the direct bromination of isobutylene.[119] However, some substitution also takes place and the isobutylene dibromide is always accompanied by higher brominated products. The approximate compositions by weight of the products of bromination of isobutylene at 45° to 50° C. and at 0° to 5° C. are given by Mereshkowsky[120] and by Hurd and Spence,[121] respectively, as follows:

	At 45° to 50° C. (Mereshkowsky)	At 0° to 5° C. (Hurd and Spence)
Isobutylene dibromide	45	65.5
Tribromoisobutane	44	25.5
Tetrabromoisobutanes	7	6.0
Penta- and hexa-bromoisobutane	1	3.0

Isobutylene dibromide is a colorless liquid, boiling point 150° C. at 760 mm.; melting point —70° C.; d^{20}_4 1.783; n^{15}_D 1.51406; n^{20}_D 1.51186.[122]

THE DIHALIDES OF THE AMYLENES

The chlorination of the various isomeric amylenes illustrates the rule of Kondakoff, already mentioned in the case of isobutylene, that the olefins which react very readily with mineral acids do not readily form the normal olefin dichlorides but tend to yield chloro-olefins instead. Thus Kondakoff[123] found that when pure trimethylethylene was treated with chlorine at 16° C. and —20° C., considerable quantities of hydrogen chloride were evolved and the products of chlorination consisted chiefly of chloroamylene and tertiary amyl chloride, with some amylene dichloride, the mechanism of formation of which may be summarized in the following manner:

[123] *J. Russ. Phys.-Chem. Soc.*, 1885, 17, 144 and 290; 1887, 19, 337; *Chem. Soc. Abs.*, 1885, 48, 736; 1886, 50, 136; 1888, 54, 123.

$C_5H_{10} + Cl_2 \longrightarrow C_5H_{10}Cl_2$ (*amylene dichloride*)

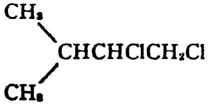
$C_5H_{10}Cl_2 - HCl \longrightarrow C_5H_9Cl$ (*chloroamylene*)

$C_5H_{10} + HCl \longrightarrow C_5H_{11}Cl$ (*tertiary amyl chloride*)

It was observed that the evolution of hydrogen chloride commenced only after a certain amount of chlorine had been absorbed, but once started this production of hydrogen chloride continued until the end of the operation. Besides the products enumerated above, others of higher boiling point (and consisting of $C_5H_{10}Cl$, $C_5H_9Cl_3$, $C_5H_8Cl_4$, with traces of C_5H_9Cl and $C_5H_{11}Cl$) are obtained if excess of chlorine is used or if the trimethylethylene is cooled with calcium chloride and snow.

When symmetrical methylethylethylene was treated with chlorine the chief product was the dichloride, $CH_3CHClCHClCH_2CH_2$, but a small quantity of the monochloropentene, $CH_3CHClCH{=}CHCH_3$ was also formed.[124]

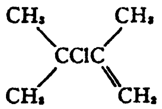
On the other hand, Kondakoff [125] found that isopropylethylene, which is also known to be less reactive toward mineral acids than methylethylethylene, gave the dichloride almost exclusively. Chlorine was passed into isopropylethylene maintained at temperatures from —20° C. to 16° C. but in all cases the products were the same, i.e., mainly isopropylethylene dichloride,



$$(CH_3)_2CHCHClCH_2Cl$$

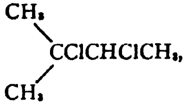
together with only a small amount of a monochloride.

It is interesting to note that tetramethylethylene, one of the more reactive of the isomeric hexenes, on treatment with chlorine at ordinary temperature, yields mainly a chlorotetramethylethylene,[126] probably



$$(CH_3)_2CClC{=}(CH_3)_2$$

Trimethylethylene Dichloride



Trimethylethylene dichloride, $(CH_3)_2CClCHClCH_3$, is a heavy oil, boiling point 133° to 135° C. at 760 mm.

According to the Badische Co.,[127] amylenes and hexenes readily yield dichlorides on treatment with sulphuryl chloride at temperatures below 30° C. The preparation of trimethylethylene dichloride can be conducted as follows: Sulphuryl chloride is gradually introduced with continuous stirring into an excess of trimethylethylene at —2° to 0° C. After a further period of agitation the sulphur dioxide and excess amylene are distilled off and the residue fractionated under reduced pressure. A good yield of trimethylethylene dichloride, boiling point 48° to 52° C. at 40 mm., is obtained.

---

[124] Kondakoff, *Ber.*, 1891, **24**, 929; *Chem. Soc. Abs.*, 1891, **60**, 809.

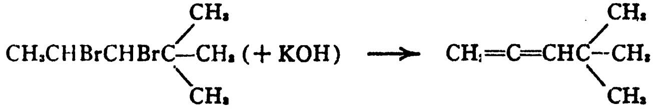
[125] *J. Russ. Phys.-Chem. Soc.*, 1888, **20**, 141; *Chem. Soc. Abs.*, 1889, **56**, 113.

[126] Choupotsky and Mariutza, *J. Russ. Phys.-Chem. Soc.*, 1890, **21**, 431; *Chem. Soc. Abs.*, 1890, **58**, 727.

[127] French Patent 433,309, 1911; *J.S.C.I.*, 1912, **31**, 151.

Isopropylethylene dichloride boils at 143° to 144.5° C. at 760 mm. and has d_4^0 1.1106, while symmetrical methylethylethylene dichloride has boiling point 138° to 139.5° C. at 760 mm.

Most of the industrial work so far reported on the chlorination of pentenes has as its primary object the production of monochloro compounds from which the monohydric alcohols can be obtained by hydrolysis. This is particularly so in the case of the amylenes and pentanes, as pointed out in Chapters 29 and 33. As indicated above the dihalides are substances of quite remarkable chemical activity which might be used for the synthesis of numerous new organic compounds. The higher homologues of allene may be synthesized from some of the olefin dihalides by treatment with caustic alkalies. In this way Favorskii[128] was able to prepare tertiary butylallene in 90 per cent yield by treating the dibromide of symmetrical methyl tertiary butylethylene with excess of caustic potash, the reaction proceeding according to the scheme:



$$CH_3CHBrCHBrC(CH_3)_3\ (+\ KOH) \longrightarrow CH_2{=}C{=}CHC(CH_3)_3$$

Higher Olefin Dihalides

The general properties of the higher olefin dihalides[129] are similar to those of the dihalides just described (such as those of tetramethylethylene and methylethylethylene). As yet they have not been employed industrially though they have been utilized in the chemical synthesis of organic substances.

A number of processes have been proposed for producing chlorinated hydrocarbons, or mixtures of such substances, by the interaction of chlorine with cracking gas or cracked gasoline. Thus, for example, Ellis and Wells[130] produced halogenated hydrocarbons by subjecting "acid extract" to the action of a halogenating agent. The term "acid extract" is here applied to an alkylsulphuric acid liquor obtained by absorption of olefins, from cracking operations, in sulphuric acid. Payne and Montgomery[131] suggest chlorinating the gaseous products of pressure distillation (i.e., cracking gas) in the presence of a catalyst made by treating a high-boiling paraffin oil with chlorine at 300° F. until a porous solid, having the appearance of coal, is obtained. In the presence of this porous catalyst chlorination is effected at about 300° F. and the most satisfactory yield of liquid chlorinated products is said to be obtained when using three volumes of chlorine per volume of gas. The process of Payne and Montgomery evidently includes not only the chlorination of the olefins present in the gas but also the substitutive chlorination of saturated hydrocarbons.

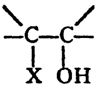
Chapter 21

Production, Properties and Uses of Halohydrins Derived from Simple Olefins

The halohydrins are compounds containing in their molecule both a halogen atom and a hydroxyl group, or in other words, are halogenated alcohols. The halohydrins derived from the simple monolefins belong exclusively to the class of 1,2- (or α) derivatives, in which the halogen atom and hydroxyl group are linked to adjacent carbon atoms and possess the following general structure:



where X represents a halogen atom. From an industrial point of view only the α-chlorohydrins exemplified by the simplest member, ethylene chlorohydrin, are of importance though the corresponding bromohydrins and iodohydrins are also known. Halohydrins in which the halogen atom and hydroxyl group are not attached to continuous carbon atoms also exist, but as they cannot be produced directly from olefins and are of little industrial interest they are not considered in the following account.

Numerous methods are available for the synthesis of the α-halohydrins, but most of them are of academic interest only. The interaction of the simple monolefins with hypochlorous acid, or chlorine water, is the only method of technical significance.

Although ethylene chlorohydrin was discovered as early as 1859 by Wurtz,[1] and its remarkable chemical reactivity clearly demonstrated, this substance continued to possess merely an academic importance until the beginning of the present century when attempts were made to use it in the synthesis of indigo. During the World War it assumed a great importance in Germany as an intermediate in the manufacture of mustard gas, but it was not until afterwards that ethylene chlorohydrin was used in comparatively large amounts for the preparation of other chemical materials. The most important factors which have contributed to a revival of interest in the olefin chlorohydrins are: first, the increasing production of large amounts of the lower olefins in commercial cracking operations (and especially in vapor-phase high-temperature cracking) and, second, the continued growth of the liquid chlorine industry with its economy of production and perfection of methods of bulk transport. Although most of the actual chemistry of the chlorohydrins has been known for half a century, changed manufacturing conditions and the development of the oil-cracking industry have combined to direct attention to the synthetic possibilities of the 1,2-chlorohydrins.

The importance of the α-chlorohydrins is due entirely to the extraordinary reactivity of the chlorine atom in these compounds, which renders possible the synthesis of a large number of organic substances, for example, solvents and drugs, from these halogenated alcohols. Possibly the greatest application of α-chlorohydrins is in the manufacture of glycols, olefin oxides, and their derivatives, which may be utilized as solvents or fumigants. In brief, the chlorohydrins derived from the simple monolefins are to be regarded as chemical intermediates in industrial syntheses possessing great potentialities.

---

[1] *Ann.*, 1859, 110, 125; prepared by the action of hydrogen chloride on glycol. Carius (*Ann.*, 1863, 126, 197) used ethylene and hypochlorous acid.

The reactions of ethylene chlorohydrin are a good example of the α-halohydrins as a class. Attention should be drawn to the reactivity of the halogen atom in the halohydrins as compared with the halogen atoms in the olefin dihalides. Whereas ethylene dichloride reacts only slowly in sodium carbonate solution at 100° C., ethylene chlorohydrin is hydrolyzed by water alone (about 15 per cent at 97° C. in 12 hours) and is quantitatively converted into ethylene glycol in one hour by sodium carbonate solution at 105° C.[2] Many other illustrations might be advanced. For example, ethylene chlorohydrin reacts with sodium sulphide to yield a thiodiglycol, with amines or caustic alkalies to form ethylene oxide, and with alkali cyanides to give the corresponding nitrile. Further, the reactivity of the chlorine atom is not greatly affected by esterifying the hydroxyl group and esters of the glycols may be prepared by the action of the sodium salts of organic acids on the chlorohydrin.

ETHYLENE CHLOROHYDRIN (α-CHLOROETHYL ALCOHOL, CH_2ClCH_2OH)

The earlier methods of preparation consisted in passing dry hydrogen chloride gas through ethylene glycol at about 150° C., the chlorohydrin distilling over as formed.[3] This rather troublesome method has been entirely superseded by the direct combination of hypochlorous acid with ethylene, a reaction discovered by Carius.[4] The earlier workers were apparently misled by the idea that fairly strong solutions of hypochlorous acid were necessary. It has since been demonstrated that the formation of chlorohydrins proceeds smoothly when olefins are passed into dilute aqueous solutions of hypochlorous acid at atmospheric temperature. Conditions which promote the solution of the gas in the aqueous solution (e.g., agitation or increased pressures) accelerate the formation of chlorohydrin.[5]

Formerly, hypochlorous acid was made by the action of chlorine water on mercuric oxide, or through the medium of chlorine oxide.[6] Lauch[7] and Bamberger[8] added a weak acid, such as boric acid, to a dilute aqueous solution of a hypochlorite. A better method is that of Wohl and Schweitzer,[9] which consists in passing chlorine into a cooled solution of sodium carbonate or bicarbonate. A variation of the latter is the adding of an excess of sodium bicarbonate to an alkaline solution of sodium hypochlorite.[10]

Before the World War the Badische Anilin- und Soda-Fabrik worked on the production of ethylene chlorohydrin with the object of synthesizing indigo, the source of hypochlorous acid being calcium hypochlorite.[11] The method for large scale preparation of ethylene chlorohydrin, developed in Germany during the World War, consisted essentially in the liberation of hypochlorous acid from bleaching powder by gaseous carbon dioxide in the presence of ethylene gas. This process has been described by Norris[12] as follows:

> The reaction was carried out in a cylindrical tank resting on its side, furnished with stirrers and well insulated. Enough chloride of lime was introduced to furnish 500 kilograms of available chlorine, together with 5 cubic meters of water. At first about 20 cubic meters of carbon dioxide alone were passed in and later, carbon dioxide and ethylene simultaneously. The reaction should be carried out at as low a temperature as possible and in practice the temperature could be maintained at 5° to 10° C. by continuously pumping the liquid through a coil cooled by brine. The rate of absorption of the ethylene was carefully noted and more carbon dioxide was introduced as soon as ethylene absorption slackened. When ethylene was no longer absorbed, i.e., in about 2 to 3 hours, the contents of the apparatus were filtered to remove calcium carbonate whereupon the residual liquor, containing 10 to 12 per cent of chlorohydrin, was distilled with steam to yield a condensate containing 18 to 20 per cent of chlorohydrin. The yield of chlorohydrin calculated on the ethylene used was 60 to 80 per cent of the theoretical.

According to Brooks,[13] the gradual liberation of hypochlorous acid from sodium hypochlorite in the presence of ethylene or propylene by weak acids (boric acid or carbon dioxide) gives yields of only 25 to 30 per cent based on the original quantity of hypochlorite. Somewhat better results are obtainable by using bleaching powder and carbon dioxide. This is probably due to the case of decomposition of sodium hypochlorite solutions the instant free hypochlorous acid is formed by the neutralization of the excess alkali. In the presence of excess free alkali, concentrated sodium hypochlorite solutions are quite stable.[14]

The principal methods which have been preposed for obtaining aqueous solutions of hypochlorous acid are as follows: passage of carbon dioxide into aqueous solutions of calcium or sodium hypochlorite; passage of chlorine into sodium carbonate solutions; introduction of chlorine and caustic alkali simultaneously; introduction of aqueous sodium bicarbonate into aqueous sodium hypochlorite. Other procedures are the introduction of chlorine into water either alone or in the presence of certain metallic salts, e.g., copper chloride or oxychloride,[15] or salts such as disodium hydrogen phosphate capable of neutralizing the hydrogen chloride simultaneously formed.[16]

The important fact that ethylene chlorohydrin may be produced by passing chlorine and ethylene simultaneously into water was established by Gomberg.[17] Previously, Read and Williams[18] had shown an analogous reaction takes place between bromine water and ethylene. Although it is well known that in the system,

$$Cl_2 + H_2O \rightleftharpoons HOCl + HCl$$

the proportions of hypochlorous and hydrochloric acids actually present under normal conditions are very small, the velocity of the reaction between the hypochlorous acid and ethylene is so much greater than that between free chlorine and ethylene that it was possible to obtain good yields of chlorohydrin and to suppress the competitive reaction of direct chlorination. According to Gomberg, when ethylene and chlorine are passed into water, keeping the ethylene in slight excess, a concentration of chlorohydrin of 6 to 8 per cent is reached before an appreciable amount of dichloride is formed. Up to this point the gases are absorbed rapidly at 10° to 12° C., but thereafter the reaction becomes sluggish. The influence of dissolved chlorohydrin, hydrogen chloride or metallic chlorides on the course of the reaction was roughly determined. Chlorohydrin itself is rather helpful at the beginning, and hydrochloric acid up to concentrations of 2 moles per liter does not hinder the almost exclusive formation of chlorohydrin. The combined effect is, however, more important since, when both are present in concentrations of 1 mole per liter production of dichloride is favored. Any attempt to shift the equilibrium $H_2O + Cl_2 \rightleftharpoons HOCl + HCl$ by removing the hydrochloric acid from the sphere of the reaction by the addition of metallic salts is not beneficial as these promote dichloride formation. Efficient stirring is necessary for good yields. Gomberg considered more than 8 per cent concentration of ethylene chlorohydrin in the reaction mixture inadvisable.

An interesting extension of Gomberg's method for the preparation of chlorohydrins is described by Ernst,[19] who effects the synthesis of chlorohydrin-ethers by causing a mixture of an olefin and chlorine to react with an alcohol, with or without the addition of water. Thus, ethylene and chlorine are passed into ethanol to furnish an 85 per cent yield of β-chloroethyl ether, $C_2H_5OCH_2CH_2Cl$.

Brooks[20] has given some details of the operation of a plant for the production of ethylene and propylene chlorohydrins by the use of chlorine water. The apparatus was of the liquid-circulating type. To minimize the corrosion difficulties the free hydrochloric acid was neutralized with soda ash. It was shown that the formation of chlorohydrins was fairly rapid until the solution contained about 5 per cent of chlorohydrins. According to Curme,[21] temperature has only a slight influence on the yield of ethylene chlorohydrin by this process and a little dichloride is always formed as a by-product.

An examination of the synthesis of ethylene chlorohydrin from hypochlorous acid and ethylene was made by Bozza and Mamoli.[22] They observed that the direct attack of ethylene by chlorine and also the action of chlorine on chlorohydrin became appreciable only when the concentration of the latter was about 1 molar. In the presence of solutions of pure hypochlorous acid the velocity of the chlorohydrin-forming reaction was independent of the concentration of the acid within wide limits but did depend upon the surface area of the ethylene bubbles. The velocity of this reaction is not altered by adding benzene or carbon tetrachloride or by starting with solutions already acid. It is diminished by the presence of sodium chloride, so that it is disadvantageous to neutralize the acid with alkali. The presence of copper salts induces considerable formation of secondary products while neutralization with lead oxide is valueless. The action of chlorine on chlorohydrin solutions of medium concentration yields highly chlorinated products very difficult to separate by distillation. Bozza and Mamoli concluded that, to avoid losses due to secondary reactions, the practical limit of chlorohydrin concentration was 8 to 10 per cent.

Shilov[23] recorded some experiments directed toward the development of an industrial method of manufacturing ethylene chlorohydrin. Hypochlorous acid was made by adding alkali or alkaline hypochlorite to a solution of chlorine in water rather than by passing chlorine into an alkaline solution. This operation was effected by first passing chlorine into a flask cooled by ice and containing a little water; after the formation of a chlorine hydrate precipitate, a solution of sodium hydroxide, or better, of sodium hypochlorite, was added (with good stirring) at such a rate that chlorine always remained in excess. When the reaction was completed, excess chlorine was removed by air-blowing or by adding a small quantity of calcium carbonate. By this method about 5.25 per cent solutions of hypochlorous acid, sufficiently stable for the chlorohydrin synthesis, were prepared. The reactions taking place were considered to be

$$Cl_2 + 2NaOH \longrightarrow NaOCl + NaCl + H_2O$$
$$Cl_2 + NaOCl + H_2O \longrightarrow 2HOCl + NaCl$$

Experiments indicated that the velocity of ethylene absorption in hypochlorous acid increased with the rate of stirring, and the formation of chlorohydrin was catalyzed by hydrogen ions. When the hydrogen-ion concentration (and consequently the hypochlorous acid concentration) drops below the neutral reaction point, ethylene absorption becomes very slow. The yield of chlorohydrin, calculated from the hypochlorous acid present, was 80 per cent when using dilute solutions. It was found also that the chlorohydrin is only slightly oxidized by the free hypochlorous acid.

Conditions for the preparation of ethylene chlorohydrin by the action of chlorine and water on ethylene have been investigated by Zapadinskii.[24] He carried out this reaction in the following manner: Chlorine and ethylene are passed simultaneously (through tubes terminating in narrow outlets) into the bottom of a 1.5 liter flask containing 500 cc. of water, maintained at ±2° C. and vigorously stirred. The pressure was 150 to 200 mm. of water. Experiments with ethylene dichloride (to increase the solubility of chlorine) and with alcohol (to increase the solubility of ethylene) resulted in considerably decreased yields since the ethylene dichloride suppresses the hydrolysis of the chlorine, and the alcohol undergoes oxidation at the expense of the chlorine. Brooks' suggestion to employ gasoline as a solvent is considered by Zapadinskii to be of doubtful value. In order to separate the chlorohydrin produced, three operations are proposed. The reaction mixture is distilled, and the first 10 to 12 per cent of distillate contains 80 to 85 per cent of the chlorohydrin; the next 10 to 15 per cent contains most of the remainder and only 2 to 3 per cent is found in the residue. The second distillate fraction is added to fresh crude material while the first distillate is extracted with ethylene dichloride, which is itself a by-product of the process. It is advisable to extract twice with this dichloride, containing some chlorohydrin, then twice with pure dichloride, taking each time a volume of solvent equal to 20 per cent of the solution. The third and final operation consists in separating the chlorohydrin from the dichloride by distillation, either at ordinary or reduced pressures.

The synthesis of ethylene chlorohydrin by Gomberg's method has been systematically studied by Tropsch and Kassler.[25] Their results are in substantial agreement with those of other investigators. Measured volumes of ethylene and chlorine were conducted into a water-filled bottle, mechanically shaken, and analyses were made of the gases escaping at the outlet. The occurrence of the two competitive reactions yielding ethylene chlorohydrin and ethylene dichloride, respectively, was noted and the influence of various factors on the relative yields of these two products investigated. Conditions found to favor the production of ethylene chlorohydrin were (1) the use of excess ethylene in the entering gases, and (2) the maintenance of a low concentration of ethylene chlorohydrin in the reaction mixture. On the other hand, the yield of ethylene dichloride rose linearly with increasing concentration of ethylene chlorohydrin.

---

[24] *J. Chem. Ind. (Moscow)*, 1928, 5, 1426; *Chem. Abs.*, 1929, 23, 3208.

[25] *Mitt. Kohlenforschungsinst. Prag.*, 1931, No. 1, 16; *Chem. Abs.*, 1932, 26, 1242; French Patent 732,106, 1932; *Chem. Abs.*, 1933, 27, 732; also British Patent 377,595, 1932; *Brit. Chem. Abs.* B, 1932, 973.

The following empirical formula was developed to express the relationship between the ratio, *y*, of the extent to which the competitive reactions, yielding chlorohydrin and dichloride respectively, proceed at a chlorohydrin concentration, *x*, and at definite partial pressures of chlorine and ethylene:

$$y = -1.312x + 0.182P + 8.66,$$

$$\text{where}\quad P = \frac{100\,p_{C_2H_4}}{p_{C_2H_4} + p_{Cl_2}},\ \text{and}$$

$p_{C_2H_4}$ and p_{Cl_2} are the partial pressures of ethylene and chlorine, respectively. Thus, in an experiment at 20° C., the reaction producing ethylene dichloride occurred to the extent of 20 per cent (based on the ethylene reacting) when the concentration of ethylene chlorohydrin was 7 per cent. For economical production of ethylene chlorohydrin, therefore, a limited concentration of it in the reaction mixture should be maintained by continuous dilution. The introduction of ethylene dichloride into the reaction mixture increased the formation of dichloride, probably by solution and direct combination of ethylene and chlorine in the oily phase. In agreement with other investigators, Tropsch and Kassler observed that the reaction rate of hypochlorous acid and ethylene was very rapid up to 10 per cent concentration. Temperature variations from 4° C. to 30° C. had little influence on the reaction, but the yield of dichloride at 40° to 60° C. was distinctly reduced.

According to Frahm,[26] the rate of formation of ethylene chlorohydrin is increased, and that of the dichloride diminished, if ethylene and chlorine are allowed to react in dilute aqueous solutions of various catalysts, e.g., in 0.1 to 1.0 per cent copper chloride or ferric chloride solutions. Since these substances facilitate the decomposition of hypochlorous acid into hydrochloric acid and oxygen, Frahm suggested that ethylene and chlorine in aqueous media give ethylene oxide, which subsequently reacts with hydrogen chloride.

TECHNICAL PRODUCTION OF CHLOROHYDRINS

The majority of the methods dealing with the manufacture of chlorohydrins refer to the treatment of cracking gas or oil gas as a source of olefinic hydrocarbons. The products, therefore, consist not only of ethylene but also of propylene chlorohydrin and possibly chlorohydrins of the immediately higher homologues of propylene. For this reason the procedures are discussed as a whole.

Walker[27] prepared chlorohydrins of the higher olefins (boiling point 35° to 125° C.) containing 5 to 8 carbon atoms per molecule by the following method. Hypochlorous acid is made by adding sodium bicarbonate (75 parts of $NaHCO_3$ to 75 parts of NaOCl) either in solid form or in aqueous solution to an aqueous 15 to 25 per cent solution of sodium hypochlorite. The hypochlorite solution is then added to the olefinic hydrocarbon with agitation and cooling. The reac-

[26] *Rec. trav. chim.*, 1931, 50, 261; *Brit. Chem. Abs.* A, 1931, 598.
[27] U. S. Patents 972,952 and 972,953, Oct. 18, 1910.

tion should continue for about four hours at a temperature of 15° C. or below. The mixture separates into two layers, an aqueous layer which is withdrawn and an oily layer (consisting of chlorohydrins and hydrocarbons). The latter is washed with water, dehydrated, and the chlorohydrins (boiling point about 170° C.) separated from lower-boiling hydrocarbons by distillation.

Kerfoot and his co-workers[28] prepared chlorohydrins, particularly ethylene chlorohydrin, by alternately passing chlorine and ethylene into an aqueous solution of a copper salt, either chloride or oxychloride. The mixture is vigorously agitated to secure good contact. A modification consists in allowing the aqueous solution to flow down a packed tower divided into a number of horizontal zones alternately filled with chlorine and ethylene. The chlorohydrins are separated from the aqueous solution by extraction with ether, or in the case of ethylene chlorohydrin, a constant-boiling mixture (43 per cent chlorohydrin and 57 per cent water, boiling point 97° C.) is obtained by fractional distillation.

McElroy[29] described the production of chlorohydrins by interaction of olefins (either pure individuals or mixtures) with aqueous solutions of chlorine or hypochlorous acid, generated electrolytically. Olefin dichlorides are formed simultaneously and it is largely a question of the relative concentrations of the chlorine, water, and olefin which determines the course of the reaction. In the presence of a large excess of water the chlorohydrin-forming reaction predominates. The aqueous bath is saturated with an excess of olefin by agitation, this being advantageous since it increases the rate of formation of chlorohydrin and also shields the latter substance from further chlorination.

It is also proposed to make chlorohydrins by allowing olefin gases to react with chlorine in the presence of excess steam and water at a temperature of about 100° C.[30] The following conditions appear to be necessary: (1) The concentrations of steam and ethylene should always be very much greater than that of the chlorine; (2) olefin dichlorides are formed unless steam is in considerable excess; (3) chlorine should always be in relatively low concentrations; (4) the reaction develops much heat which is absorbed by the steam; (5) the continued condensation (and evaporation) of water carries the hydrogen chloride formed into the liquid phase so that it may be continuously removed from the reaction zone.

McElroy[31] suggested carrying out the same reaction in a tower at the bottom of which the mixed olefin gases are introduced. The gases pass upwards against a downflowing current of hot water which furnishes the water vapor necessary for dilution and reaction and also serves as a scrubbing means to remove hydrogen chloride. Chlorine is added at various points in the tower and the temperature is so maintained that the desired products together with water vapor pass from the top of the tower and are condensed. Hydrochloric acid is removed continuously at the bottom.

In connection with these processes of McElroy, Brooks[32] has recorded that large-scale operation leads to the formation of large proportions of highly chlorinated oily products.

Another process for making chlorohydrins depends essentially on the employment of metallic chlorides, such as cupric or ferric chlorides, for supplying the chlorine.[33] The reduced chloride (cuprous or ferrous chlorides) is then reconverted into the initial materials by oxidation with air followed by treatment with hydrochloric acid. Thus, a mixture of olefins and steam is conducted over cupric chloride (or ferric chloride) suspended on a carrier, at temperatures of over 100° C., best at about 160° C.

[32] *Chem. Met. Eng.*, 1920, **22**, 631.

[33] McElroy, U. S. Patent 1,315,229, Sept. 9, 1919; *Chem. Abs.*, 1919, **13**, 2880.

The process of Moness[34] consists in passing a mixture of gaseous olefins (cracking gas), chlorine, and steam, into a reaction chamber at 97° to 100° C. packed with materials, such as manganese dioxide, which are capable of reacting with the hydrochloric acid produced to yield more chlorine. Various other substances may be employed to combine with the hydrochloric acid, e.g., magnesium oxide or zinc oxide, or oxidizing compounds such as chromates or ferric oxide. The products consist of an aqueous solution of chlorohydrins together with a separate oily layer containing olefin dichlorides.

Brooks[35] described a treatment of ethylene or cracking gas which consists in passing these olefins, under 5 to 10 atmospheres pressure, into chlorine water at 10° to 20° C., with violent agitation and in the presence of an immiscible solvent for chlorohydrins, e.g., chloroform, carbon tetrachloride, tetrachloroethane, dichloroethane, benzol, and toluol. The presence of the immiscible solvent tends to remove the chlorohydrin from the aqueous solution and thus prevents its being further acted upon by chlorine.

In another procedure,[36] unsaturated hydrocarbons are mixed with an aqueous solution of an alkali carbonate or bicarbonate, and chlorine is then introduced into the aqueous (i.e., bottom) layer. Reaction between the dilute hypochlorous acid solution and the unsaturated hydrocarbons is facilitated by vigorous agitation or by circulating or atomizing one liquid through the other. The maximum strength of hypochlorous acid is about 3 per cent. The chlorohydrins produced are said to be substantially free from dichlorides.

As a method of isolating chlorohydrins, Brooks[37] suggested adding a neutral salt (sodium or magnesium chloride or sulphate) to the aqueous solution, separating the oily layer which forms, and then extracting the latter with a solvent immiscible with water, such as benzol or carbon tetrachloride. The use of benzol as a dehydrating agent has been suggested also by Kirst.[38]

In the process of Eldred,[39] chlorohydrins are obtained by adding successive portions of chlorine and olefin-containing gases, such as oil gas, to a flowing stream of steam, while permitting time for reactions between successive additions.

Curme and Young[40] employ a solution of a hypochlorite containing free hypochlorous acid, and Eldred and Brooks[41] use solutions of an alkali salt of a weak acid (e.g., sodium carbonate, bicarbonate, borate or phosphate) which has previously been treated with chlorine and therefore contains free hypochlorous acid.

The following procedure was described by Long, Willson and Wheeler.[42] Water is circulated through a number of reaction vessels, in some of which it is treated with halogen while in others (alternately spaced) the halogenated liquid, containing free hydrochloric and hypochlorous acid, is treated with an olefin at 0° to 20° C. These steps are repeated until the concentration of halohydrin reaches a value above which the formation of hypochlorous acid is depressed by the accumulated hydrochloric acid. The concentration of the latter should not exceed 1 molar and is maintained by addition of water and withdrawal of treated liquid. Anhydrous halohydrins are obtained by conversion into olefin oxide followed by treatment with dry hydrogen halide.

[42] British Patent 265,259, 1925; *Chem. Abs.*, 1928, **22**, 244.

Olefin chlorohydrins are obtained as intermediate products in the manufacture of 1,2-glycols prior to hydrolysis.[43] For example, in the production of ethylene glycol, 482 cubic feet of ethylene and 241 cubic feet of carbon dioxide are passed into a cold 5 per cent hypochlorite solution, containing 100 pounds of sodium hypochlorite. The ethylene is admitted in the form of fine bubbles while the carbon dioxide is introduced sufficiently slowly into the cooled liquid to maintain a low concentration of hypochlorous acid. The solution of ethylene chlorohydrin is then boiled for several hours to effect hydrolysis to the glycol. Polyhydroxy-compounds, e.g., glycerol from allyl alcohol, are made in a similar manner.[44]

In the process of Youtz,[45] ethylene is dissolved in an aqueous medium at a pressure of 100 to 200 atmospheres and the resulting solution, free from undissolved gaseous olefin, is allowed to react with hypochlorous acid. The application of pressure is also advocated by the T. Goldschmidt A.-G.[46]

Isham and Spring[46a] prepared chlorohydrins by treating an alkylene dichloride (ethylene dichloride) with sulphur trioxide at 35° to 45° C. and subsequently hydrolyzing the chloroethylsulphuric chloride. The chlorohydrin may be separated from the mixture by fractional distillation.

Another suggestion for preparing chlorohydrins consists in reacting esters of hypochlorous acid and tertiary alcohols with organic compounds containing one or more double bonds, such as olefins, diolefins, or oleic acid.[46b]

Recovery of Ethylene Chlorohydrin

Various methods have been proposed for recovering ethylene chlorohydrin from the comparatively dilute solutions obtained in its preparation. A constant-boiling mixture of ethylene chlorohydrin and water, containing 42.5 per cent chlorohydrin and 57.5 per cent water, boiling point 95.8° C. (735 mm.), is known.[47] When dilute aqueous solutions are distilled, it is a comparatively easy matter to obtain a distillate containing 20 to 25 per cent of chlorohydrin. Saturation of a 35 per cent solution of chlorohydrin with salt causes a separation into two layers, the oil layer containing about 70 per cent chlorohydrin. When this 70 per cent solution of chlorohydrin is distilled the azeotropic mixture first comes over, and finally anhydrous chlorohydrin, boiling point 128° to 128.5° C.[48] Other methods of obtaining pure chlorohydrin are distillation with benzene,[49] and extraction with organic solvents such as ether.[50] Another procedure which has been advanced is to convert the dilute chlorohydrin into ethylene oxide and then treat this compound with dry hydrogen chloride.[51]

PROPERTIES OF ETHYLENE CHLOROHYDRIN

Ethylene chlorohydrin is a colorless liquid of d^{20}_{4} 1.1980, boiling at 132° C. at 761 mm and 51° to 52° C. at 22 mm. It forms a constant-boiling mixture with water (42.5 per cent chlorohydrin and 57.5 per cent water) which boils at 95.8° C. at 735 mm.[52]

Some of the physical constants of solutions of ethylene chlorohydrin in water and in saturated brine have been determined by Bozza and Gallarati.[53] The refractive index of aqueous solutions varies practically linearly with the composition by weight, the value (N^{20}_{D}) for pure chlorohydrin being 1.4421. Table 102 shows the boiling points of azeotropic mixtures in pure water and in saturated sodium chloride at various pressures.

TABLE 102.—*Boiling Point of Ethylene Chlorohydrin Azeotropes.*

Solvent	760 mm. ° C.	504 mm. ° C.	400 mm. ° C.
Water	97.8	86.4	80.55
Saturated sodium chloride solution in water	101.4	90.7	85.4

The azeotropic mixture from pure water solutions at 400 mm. pressure contains 40.5 per cent by weight of ethylene chlorohydrin, while that obtained from saturated brine at the same pressure contains 57.8 per cent. This displacement of composition of the azeotrope in the presence of sodium chloride makes possible the concentration of chlorohydrin solutions by alternate distillation from aqueous and sodium chloride solutions.

Anhydrous ethylene chlorohydrin possesses marked solvent properties but the ease with which it hydrolyzes with the formation of corrosive hydrochloric acid greatly restricts its usefulness.[54] Ethylene chlorohydrin is a solvent for cellulose acetate and the solutions have a high tolerance for water, while cellulose acetates containing over 50 per cent of combined acetic acid dissolve in equal parts of chlorohydrin and water.[55] This chlorohydrin is miscible with benzene, water and alcohol. It possesses marked toxic properties,[56] due probably to its hydrolysis in the tissues with the production of hydrochloric acid. It has been noted [57] that ethylene chlorohydrin possesses the power of shortening the dormant period of potato tubers and of inducing early sprouting and budding. Juice from potato tubers which were treated with 1.6 per cent of ethylene chlorohydrin, kept in a closed container for 24 hours and then planted in moist soil for 5 days, was found to contain glutathione,[57a] which cannot be found in untreated potatoes. This chlorohydrin increases the rate of hydrolysis of starch by the enzyme, amylase.[58]

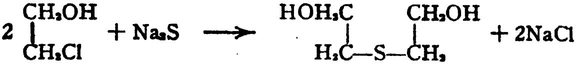
The chemical properties of ethylene chlorohydrin are typical of those of the α-halohydrins as a class. All these substances possess a chemical reactivity which can be traced to the lability of the halogen atom in these compounds. The reactivity of the chlorine atom is not greatly affected by esterifying the hydroxyl group, a fact which is utilized in the manufacture of novocain by the action of diethylamine on the p-aminobenzoic ester. When the hydroxyl group and chlorine atom in chlorohydrins are separated by one or more CH_2 groups, the chemical reactivity of the halogen atom is reduced to approximately that of the alkyl chlorides.

Ethylene chlorohydrin is finding application as a chemical intermediate in the preparation of a number of synthetic products, particularly ethylene glycol,[59] ethylene oxide[60] and their derivatives. The glycol and the oxide result from the action of alkalies on ethylene chlorohydrin. Weak alkalies (e.g., sodium bicarbonate solutions) yield ethylene glycol, solid soda or potash furnish ethylene oxide, while dilute solutions of strong alkalies yield gummy condensation products of unknown nature. When hydrolyzed by water at 100° C., ethylene chlorohydrin yields acetaldehyde in addition to glycol.[61] Steimmig and Wittwer[61a] obtained an 80 per cent yield of ethylene glycol carbonate, a solid melting at 38.5° to 39° C.[61b] and boiling at 236° C., on heating equimolecular proportions of ethylene chlorohydrin and sodium bicarbonate for several hours.

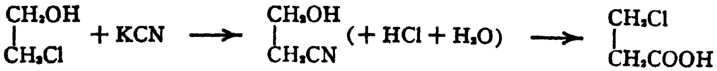
The activity of the halogen atom in ethylene chlorohydrin is demonstrated by the following reactions, which may be regarded as typical of α-chlorohydrins: (a) With sodium sulphide to give thiodiglycol,[62] a substance which was used in the preparation of mustard gas. A 79 to 86 per cent yield of β-thiodiglycol is obtained by treating 1500 grams of a 20 per cent aqueous solution of ethylene chlorohydrin with 750 grams of water containing 493 grams of sodium sulphide ($Na_2S.9H_2O$), with stirring, at 30° to 35° C. and then heating for 45 minutes at 90° to 95° C.[63]



$$2\;\begin{array}{l}CH_2OH\\ |\\ CH_2Cl\end{array} + Na_2S \longrightarrow \begin{array}{ccc}HOH_2C & & CH_2OH\\ | & & |\\ H_2C & -S- & CH_2\end{array} + 2NaCl$$

(b) With sodium iodide to furnish the corresponding iodohydrins.[64]

(c) With alkali cyanides to yield cyanohydrins. Thus, Jacobs and Heidelberger[65] by refluxing ethylene chlorohydrin with potassium cyanide in alcoholic solution for 8 hours, obtained ethylene cyanohydrin which, on treatment with concentrated hydrochloric acid, gave α-chloropropionic acid.



$$\begin{array}{l}CH_2OH\\ |\\ CH_2Cl\end{array} + KCN \longrightarrow \begin{array}{l}CH_2OH\\ |\\ CH_2CN\end{array} (+ HCl + H_2O) \longrightarrow \begin{array}{l}CH_2Cl\\ |\\ CH_2COOH\end{array}$$

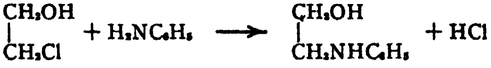
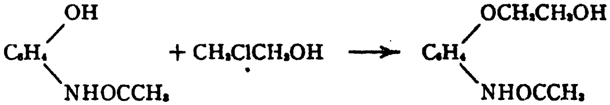
(d) With primary and secondary amines to give amino-alcohols, a reaction which has been employed for the manufacture of novocain. On reacting equimolecular proportions of aromatic di- or poly-amines with ethylene chlorohydrin in the presence of a solvent and an acid-binding agent, the mono-hydroxyalkyl derivatives are formed.[65a] Kamm, Adams and Volwiler,[66] by condensing ethylene chlorohydrin with dibutylamine and esterifying the product with p-aminobenzoic acid, have prepared a novocain-like substance containing a dibutylamino group instead of diethylamino. The reaction is also exemplified by the combination of ethylene chlorohydrin with aniline to yield β-anilinoethanol, which may be represented as:[67]

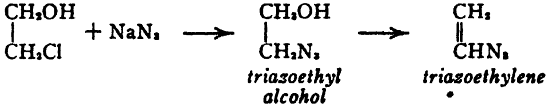


$$\begin{matrix} CH_2OH \\ | \\ CH_2Cl \end{matrix} + H_2NC_6H_5 \longrightarrow \begin{matrix} CH_2OH \\ | \\ CH_2NHC_6H_5 \end{matrix} + HCl$$

(e) With alkali phenolates to form ethers of the type $C_6H_5OCH_2CH_2OH$. A somewhat similar reaction is that with p-hydroxyacetanilide to form p-β-hydroxyethoxyacetanilide.[68]

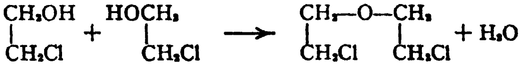


(f) With sodium azide to replace the chlorine atom by the triazo group.[69] The resulting triazoethyl alcohol has been made the starting point for the synthesis of triazoethylene, boiling point 26° C.



$$\begin{matrix} CH_2OH \\ | \\ CH_2Cl \end{matrix} + NaN_3 \longrightarrow \begin{matrix} CH_2OH \\ | \\ CH_2N_3 \end{matrix} \longrightarrow \begin{matrix} CH_2 \\ \| \\ CHN_3 \end{matrix}$$

(g) With concentrated sulphuric acid at 90° to 100° C. to result in a 75 per cent yield of ββ′-dichlorodiethyl ether,[70] an industrial solvent.



$$\begin{matrix} CH_2OH \\ | \\ CH_2Cl \end{matrix} + \begin{matrix} HOCH_2 \\ | \\ CH_2Cl \end{matrix} \longrightarrow \begin{matrix} CH_2\text{—}O\text{—}CH_2 \\ | \qquad\quad | \\ CH_2Cl \quad CH_2Cl \end{matrix} + H_2O$$

(h) The chlorohydrins may be esterified in some cases by the action of acid chlorides such as acetyl chloride. Ethers may also be produced by the substitution of the hydrogen atom of the hydroxyl group by alkyl groups. Thus by the action of dimethyl and diethyl sulphates on 1-chloro-2-hydroxypropane (propylene α-chlorohydrin) Dewael[71] has prepared the methyl and ethyl ethers, having the formulas $CH_2ClCH(OCH_3)CH_3$ and $CH_2ClCH(OC_2H_5)CH_3$, respectively.

UTILIZATION OF ETHYLENE CHLOROHYDRIN

The main use of ethylene chlorohydrin is as an intermediate in the production of ethylene glycol and its derivatives. To a much less extent it has been used in the manufacture of local anesthetics such as novocain. It reacts with aniline to form anilinoethanol (as previously mentioned), which in turn is converted into indoxyl (an intermediate in the synthesis of indigo) by alkali fusion.[72] On condensing ethylene chlorohydrin with a primary or secondary aliphatic amine containing at least one alkyl group with more than eight carbon atoms, products are formed which can be used as wetting, washing, and dispersing agents.[72a]

Another possible application is in the refining of oil fractions, such as brown-coal tar distillates. According to Steinbrecher,[73] paraffins and naphthenes may be separated from unsaturated and aromatic hydrocarbons, phenols, and sulphur and nitrogen compounds by this solvent.

Chlorohydrins are employed in the manufacture of hardenable resins by interaction with phenol alcohols, such as diphenylolpropanetetracarbinol.[74] Ellis and Weber [75] obtained a light-colored resin of low acid number by esterification of rosin with a mixture of ethylene and propylene chlorohydrins. On heating dimethylol urea in ethylene chlorohydrin to 90° C. in the presence of a small proportion of urea nitrate, neutralizing and treating the solution with ethyl alcohol, a precipitate separates. When heated in a solution of sodium linoleate to 120° C., this precipitate forms a resin resembling linoxyn which can be used in the manufacture of lacquers and plastics.[75a]

Dichlorodiethyl ether, $ClCH_2CH_2OCH_2CH_2Cl$, is a colorless liquid of boiling point 178° C., which on account of its stability and resistance to hydrolysis may be used as a high-boiling solvent It is not a solvent for the cellulose esters but in conjunction with 10 to 30 per cent of alcohol it becomes an active solvent, and has been suggested as a high-boiling diluent in lacquers.[76] This ether has also been incorporated in scouring soaps and in wetting-out agents and penetrants, especially in the treatment of cotton fabrics. Dichlorodiethyl ether has been used as a selective solvent in the refining of lubricating oils (Chlorex process),[76a] and has been proposed for the extraction of tar from pyroligneous liquids.[76b]

The chemical reactions of β,β'-dichlorodiethyl ether are similar to those of ethylene dichloride. Thus, on treatment with ammonia and amines, it yields amino-ethers and substituted amino-ethers. With sodium alcoholates or phenolates, chloralkyl or chloraryl ethers, as well as dialkyl or diaryl ethers of diethylene glycol, are formed.

Ethylene formochlorohydrin, CH_2ClCH_2OOCH, a colorless mobile liquid, boiling point 94° C. (760 mm.) and d^{1}_{4} 1.17, has been proposed as an intermediate in the production of pure ethylene chlorohydrin.[77] The chloroformate is prepared by saturating ethylene diformate with hydrogen chloride and fractionally distilling the mixture. Hydrolysis of the chloroformate with methyl alcohol (containing 1 per cent of hydrogen chloride) yields ethylene chlorohydrin.

$$\begin{array}{l} CH_2OOCH \\ | \\ CH_2Cl \end{array} + CH_3OH \longrightarrow \begin{array}{l} CH_2OH \\ | \\ CH_2Cl \end{array} + CH_3COOCH$$

Ethylene bromohydrin, CH_2OHCH_2Br, is a substance which was formerly prepared by the action of hydrogen bromide[78] or of phosphorus tribromide[79] on ethylene glycol. Mokievski[80] showed that the direct combination of aqueous hypobromous acid and ethylene occurred more rapidly and gave better yields of halohydrin (up to 60 per cent of the theoretical) than in the case of the combination of hypochlorous acid and ethylene. He prepared the hypobromous acid with the aid of mercuric oxide but it was subsequently found that the treatment of ethylene with cold bromine water gave good yields of bromohydrin. This latter method was afterwards investigated by Read and Williams,[81] who were able to obtain as high as 54 per cent yields of ethylene bromohydrin. Later Read and Hook[82] found that the reaction velocity is greater as the products accumulate for the reaction in which dibromide is formed than for the reaction yielding bromohydrin. This result is probably related to the great difference in solubility of the dibromide and bromohydrin and to the separation of the dibromide as a distinct phase. In spite of this, however, the molecular ratio of bromohydrin to dibromide, which in the initial stages of the reaction is as high as 20:1, remained greater than unity throughout the range of concentration investigated. When the concentration of bromohydrin had reached 0.2*N*, the molecular ratio of bromohydrin to dibromide was about 10:1. The reaction is best carried out at 0° C., as raising the temperature decreases the reaction rate and at the same time the ratio of bromohydrin to dibromide formed is materially reduced. Reaction is accelerated by exposure to sunlight, which does not, however, affect the relative proportions of the products.

Ethylene bromohydrin is a colorless, mobile liquid, miscible with water in all proportions. It boils with slight decomposition at 146° to 150° C. at normal pressure, at 53.5° C. at 14 mm. and 48.5° C. at 13 mm. It has d^0_4 1.7902, d^{20}_4 1.7629, n^{20}_D 1.4915 and forms a constant-boiling mixture with water, boiling point 99.1° C. (762.4 mm.), containing 35.0 per cent of bromohydrin. It may be partly salted out by saturating its aqueous solution with sodium sulphate or other salts. Bromohydrin dissolves in most of the common organic solvents but not in light petroleum. The vapors of the pure substance and also of its aqueous solutions exert a painful irritant action on the eyes and nostrils shortly after inhalation. Ethylene bromohydrin is hydrolyzed by water more readily than the chlorohydrin. The hydrolysis is perceptible, though very slow, in the cold and is accelerated by warming and by the presence of acids and alkalies.[83]

Ethylene iodohydrin, CH_2OHCH_2I, results from the action of potassium iodide on the chlorohydrin.[84] It is an oil of boiling point 85° C. (25 mm.), and d^{20}_4 2.905. Sand[85] prepared this compound by treating a mercury-ethanol compound with iodine.

PROPYLENE CHLOROHYDRINS

Propylene combines with hypochlorous acid solutions much more readily than ethylene to yield a mixture of two isomeric chlorohydrins, namely, 1-hydroxy-2-chloropropane and 1-chloro-2-hydroxypropane, the latter being the predominating product.[86]

$$CH_3CH{=}CH_2 + HOCl \begin{cases} \nearrow CH_3CHOHCH_2Cl \text{ (α-isomer, main product)} \\ \searrow CH_3CHClCH_2OH \text{ (β-isomer)} \end{cases}$$

These chlorohydrins may be prepared in several other ways, for example from propylene glycol or oxide by treatment with hydrochloric acid. Smith,[87] from measurements of rates of hydrolysis of these products, has shown that most of them consist of a mixture of both isomers though the propylene chlorohydrin prepared from allyl bromide consists almost entirely of the α-isomer. Smith gives the figures in Table 103 for the proportions of the two isomers in propylene chlorohydrins prepared in various ways:

TABLE 103.—*Proportions of Isomers in Propylene Chlorohydrins.*

Mode of Preparation	Per Cent Composition α-isomer	β-isomer
From propylene glycol and S_2Cl_2	80	20
From propylene glycol and HCl at 140° C.	70	30
From propylene oxide	90	10
From propylene and HOCl	90	10

No systematic study is apparently available on the action of hypochlorous acid on propylene though methods have been developed for the production of mixtures of ethylene and propylene chlorohydrins from cracking gas by interaction with dilute solutions of hypochlorous acid.

Of the two propylene chlorohydrins, 1-hydroxy-2-chloropropane, d^{20}_4 1.103, boils at 133° to 134° C., and 2-hydroxy-1-chloropropane, d^{20}_4 1.111, boils at 126° to 127° C. The latter, which is the main product of the action of hypochlorous acid on propylene, may also be obtained by hydrating allyl chloride with the aid of sulphuric acid at 0° C.[88]

$$CH_2{=}CHCH_2Cl + H_2O \longrightarrow CH_3CHOHCH_2Cl$$

In chemical and physical properties the propylene chlorohydrins closely resemble ethylene chlorohydrin. Thus, heating with aqueous sodium bicarbonate converts both chlorohydrins into propylene glycol,[89] while heating with anhydrous caustic alkalies furnishes propylene oxide, the best results being obtained with little or no water in the reaction mixture. When 1-chloro-2-hydroxypropane is heated with water [90] at 140° to 160° C. or with zinc or lead oxides [91] a mixture of acetone and propionaldehyde is produced.

The propylene chlorohydrins are excellent solvents for certain grades of cellulose acetate, and for many copals and resins, but the ease of hydrolysis and the consequent formation of free hydrochloric acid militates against their extensive use as solvents. These substances are hydrolyzed by water to a slightly greater extent than ethylene chlorohydrin.[89]

The methods employed for making chlorohydrins (which have been previously reviewed) are in most instances applicable to propylene chlorohydrin. Apparently the use of dilute aqueous solutions of hypochlorous acid (e.g., from sodium hypochlorite and carbon dioxide) gives good results, especially if the olefin is absorbed under pressure.

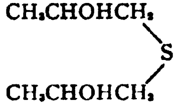
[91] Eltekov, *J. Russ. Phys.-Chem. Soc.*, 1878, 10, 211; *Ber.*, 1878, 11, 989; *Chem. Zentr.*, 1878, 516.

A number of potentially valuable materials may be synthesized from propylene chlorohydrins by reactions similar to those undergone by ethylene chlorohydrin. Thus, for example, propylene chlorohydrin may be converted into a thiodiglycol, which is said to be valuable in dyestuff-printing. According to Kränzlein and Corell,[92] this thiodiglycol, or thiohydrin, which possesses the constitution:



may be prepared by introducing 189 parts of propylene chlorohydrin into 1000 parts of a normal solution of sodium sulphide. The mixture is heated to boiling for a short time, evaporated *in vacuo*, the sodium chloride separated out, and the thiohydrin distilled *in vacuo*. At 4 mm. the boiling point of propylene thiohydrin is 120° C.

By processes analogous to those already mentioned in the discussion of ethylene chlorohydrin, the propylene chlorohydrins may be converted into numerous other organic chemicals, e.g., into cyanohydrin by treatment with sodium cyanide or into amino-derivatives by condensation with amines.

BUTYLENE HALOHYDRINS

The halohydrins of the butylenes, amylenes and other olefins are not nearly so well known as the ethylene and propylene derivatives. As the series of hydrocarbons is ascended the number of possible isomers increases considerably. The chlorohydrins of the butylene series have been prepared mainly by the combination of olefin with dilute hypochlorous acid in the cold. Apparently there is an increasing tendency for dichlorohydrocarbons to be produced in the case of the higher olefins [93] in the presence of hypochlorous acid.

When butene-1 is treated with cold aqueous hypochlorous acid, some 1,2-dichlorobutane and trichlorobutane are formed. The main product is 1-chlorobutanol-2,

$$CH_3CH_2CHOHCH_2Cl$$

a colorless liquid of boiling point 141° C. On oxidation with chromic acid, this chlorohydrin yields chloromethyl ethyl ketone, a pungent liquid of boiling point 135° to 137° C. In the same way 1-bromobutanol-2 may be prepared from butene-1 and hypobromous acid. The bromohydrin is a colorless liquid, boiling at 56° to 58° C. (11 mm.), which also undergoes oxidation by chromic acid to a bromomethyl ethyl ketone.[94]

Ordinary butene, which consists mainly of butene-2, on treatment with a 1 per cent hypochlorous acid solution yields the chlorohydrin, 2-chlorobutanol-3, a liquid of boiling point 138° to 139° C., d_0^0 1.0868.[95] This substance when heated alone to 180° C., or with water at 120° C., is converted into methyl ethyl ketone and hydrochloric acid,

$$CH_3CHClCHOHCH_3 \longrightarrow CH_3CH_2COCH_3 + HCl$$

---

[92] U. S. Patent 1,570,262, Jan. 19, 1926; assigned to Farbwerke vorm Meister, Lucius und Brüning; *Brit. Chem. Abs.* **B**, 1926, 218. British Patent 185,403, 1922; *J.S.C.I.*, 1923, **42**, 1118A.

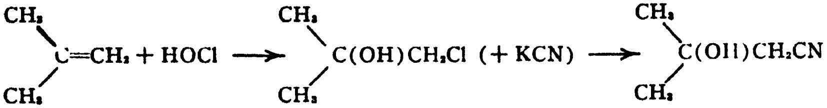
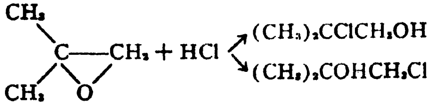
[95] Krassuski, *J. Russ. Phys.-Chem. Soc.*, 1901, **33**, 1; *Chem. Zentr.*, 1901, **1**, 995; Henry, *Compt. rend.*, 1907, **145**, 498, 763; *Chem. Zentr.*, 1907, **2**, 1489; Fourneau and Puyal, *Bull. soc. chim.*, 1922, (4) **31**, 424; *Chem. Abs.*, 1922, **16**, 2495.

According to Krassuski, isobutylene on treatment with hypochlorous acid yields mainly the chlorohydrin, 1-chloro-2-methylpropanol-2, boiling point 128° C., d_0^0 1.0878. This substance yields β-hydroxy-isovaleronitrile on treatment with potassium cyanide in alcohol. When isobutylene oxide reacts with hydrochloric acid this chlorohydrin is formed together with an isomer, namely 2-chloro-2-methylpropanol-1, boiling point 132° to 133° C. The relationship between these chlorohydrins is shown by the following scheme:

$$CH_3CH_2CH{=}CH_2 + HOCl \longrightarrow CH_3CH_2CHOHCH_2Cl$$

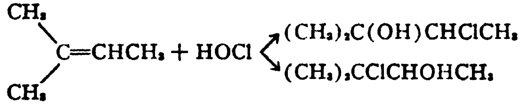
$$CH_3CH{=}CHCH_3 + HOCl \longrightarrow CH_3CHClCHOHCH_3$$





HALOHYDRINS OF THE HIGHER OLEFINS

Very little is definitely known about the higher alkylene chlorohydrins but combination between the higher olefins and hypochlorous acid appears to take place very readily with a tendency for chlorohydrocarbons to be produced. According to Krassuski [96] trimethylethylene combines with hypochlorous acid to yield two isomeric chlorohydrins, one of which is decomposed by refluxing with water to give isopropyl methyl ketone:



$$(CH_3)_2CClCHOHCH_3 \longrightarrow (CH_3)_2CCHCOCH_3 + HCl$$

The chlorohydrins of commercial amylene have been prepared by Walker,[97] who separated them from the accompanying hydrocarbons by fractional distillation and then converted them into a mixture of oxides by the action of alkalies. Kiss [97a] prepared aldehydes and ketones from olefins containing more than four carbon atoms by the action of hypochlorous acid on olefinic gasolines, the chlorohydrins thus formed being subsequently heated with water.

An interesting process for making chlorohydrins has been worked out by Detoeuf,[98] who used N-chlorourea as a source of hypochlorous acid. A solution of this compound in water, containing 10 per cent of urea hydrochloride or 5 per cent acetic acid, was shaken with the unsaturated hydrocarbon. A neutral solution of N-chlorourea reacts too slowly, and too acid solutions evolve chlorine. With this reagent Detoeuf was able to prepare the chlorohydrins of a number of olefins.[99] For example, from trimethylethylene a 70 per cent yield of the chlorohydrin  was obtained. This chlorohydrin reacted with potassium hydroxide to furnish the oxide, and with barium carbonate solution to produce the glycol. With aniline, a ketone was formed and this reaction is general in the case of the higher chlorohydrins:

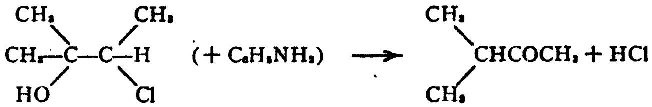
[97a] U. S. Patent 1,767,291, June 24, 1930; assigned to Standard Oil Development Co.; *Chem. Abs.*, 1930, 24, 4386.

[98] *Bull. soc. chim.*, 1922, 31, 102; *Chem. Abs.*, 1922, 16, 1395. N-chlorourea is prepared by the action of chlorine on urea in a little water at 0° C. The crystalline product is isolated by cooling the mixture with methyl chloride and filtering. See also Béhal and Detoeuf, *Compt. rend.*, 1911, 153, 681; *Chem. Abs.*, 1912, 6, 82.



It has been proposed to make amylene bromohydrins, which are said to be useful in the preparation of pharmaceutical products, by the action of hypobromites on amylene in the presence of weak acids such as boric acid.[100]

Two chlorohydrins of the hexene series have been described by Henry.[101] One of these is obtained (accompanied by some dichloride) by the action of hypochlorous acid on hexene-2 (from mannite), and probably has the constitution,

$$CH_3CHOHCHClCH_2CH_2CH_3.$$

This is a liquid of boiling point 170° C. and d^{11}_4 1.018 and is converted by the action of acetyl chloride into hexylene acetochlorohydrin. An isomeric halohydrin, prepared by the action of hydrochloric acid on hexylene oxide, probably possesses the formula,

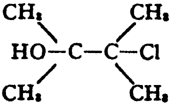
$$CH_3CH_2CH_2CHOHCHClCH_3.$$

This chlorohydrin is a colorless liquid, insoluble in water, and of d^{11}_4 1.0143. The corresponding bromohydrin is a colorless liquid of penetrating odor, insoluble in water, and of boiling point 188° to 190° C. (769 mm.) and d^{11}_4 1.2959. The corresponding iodohydrin was also prepared by Henry.

According to Detoeuf[102] the action of N-chlorourea in aqueous solution on hexene-2 furnishes a chlorohydrin having the formula,

$$CH_3CH_2CH_2CHOHCHClCH_3.$$

The product is obtainable in a 60 per cent yield although the reaction is very slow. On treatment with potassium hydroxide the oxide is formed, and in the presence of barium carbonate it is hydrolyzed to the glycol. In the same manner the chlorohydrin of tetramethylethylene has been prepared by Detoeuf in 67 per cent yield. This chlorohydrin possesses the structure:



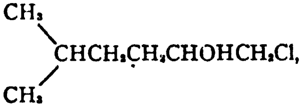
---

[99] *Bull. soc. chim.*, 1922, 31, 169, 176; *Chem. Abs.*, 1922, 16, 2113.
[100] Rath, German Patent 301,905, 1918; *Chem. Abs.*, 1919, 13, 363.
[101] *Compt. rend.*, 1883, 97, 260; *Chem. Soc. Abs.*, 1884, 46, 33.
[102] *Bull. soc. chim.*, 1922, 31, 169, 176; *Chem. Abs.*, 1922, 16, 2113.

and, in the presence of alcoholic potassium hydroxide, yields 90 per cent of the corresponding oxide.

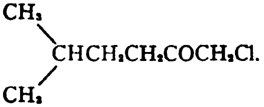
Detoeuf has succeeded in preparing a number of the higher chlorohydrins, of which the following may be mentioned:

Isoheptylene chlorohydrin,



$$\begin{matrix} CH_3 \\ & \diagdown \\ & & CHCH_2CH_2CHOHCH_2Cl, \\ & \diagup \\ CH_3 \end{matrix}$$

was obtained in an 85 per cent yield from isoheptene-1. It is a liquid of boiling point 97° to 98° C. (23 mm.), d^0_4 1.044, n^{14}_D 1.45662 and on oxidation yields a ketone[103] of the formula,



$$\begin{matrix} CH_3 \\ & \diagdown \\ & & CHCH_2CH_2COCH_2Cl. \\ & \diagup \\ CH_3 \end{matrix}$$

Octene-2 chlorohydrin, ($CH_3CH_2CH_2CH_2CH_2CHOHCHClCH_3$), is obtainable in 50 per cent yield from octene-2 and aqueous N-chlorourea. It is a liquid of boiling point 99° to 110° C. (14 mm.), d^0_4 1.001, n^{19}_D 1.45232 and, on oxidation furnishes α-chloromethyl hexyl ketone.

Styrene chlorohydrin, ($C_6H_5CHOHCH_2Cl$), can be made from styrene in a similar way, and has a boiling point of 128° C. (17 mm.), d^0_4 1.225, n^D_{17} 1.55405. On oxidation it is converted into a chloroketone,

$$C_6H_5COCH_2Cl.$$

Potassium hydroxide converts it into the oxide, while sodium ethylate reacts with it to yield an ether.

Cyclohexene chlorohydrin is the result of the reaction between cyclohexene and N-chlorourea. It is a liquid, boiling point 84° to 85° C. (16 mm.), d^0_4 1.138, and n^{20}_D 1.44097. Treatment with potassium hydroxide furnishes the oxide, while oxidation gives 2-chlorocyclohexanone.

Detoeuf has laid down the following rules which, he believes, govern the addition of hypochlorous acid to the higher olefins: (1) When the carbon atoms of the double bond are unequally substituted, the hydroxyl group becomes attached to the more substituted carbon atom. (2) When these carbon atoms are equally substituted, the hydroxyl group becomes attached to the carbon atom farthest from the end of the chain.

In regard to the elimination of hydrogen chloride from the higher chlorohydrins, Detoeuf enumerates the following rules: (1) If the medium is alkaline and the temperature low, oxides are formed. (2) If the medium is alkaline and the temperature high, conversion to a ketone takes place, often with intramolecular change. (3) If the medium tends to become acid (e.g., by dissociation of aniline hydrochloride when aniline is employed), a ketone is formed. (4) In neutral solution hydrolysis to the glycol occurs.

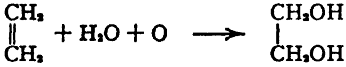
Chapter 22

Production, Properties and Uses of Simple Glycols

The glycols, or dihydric alcohols, derived from the olefins contain two hydroxyl groups attached to adjoining carbon atoms in the chain and are referred to as α- or 1,2-glycols. Although ethylene glycol, the simplest and most important member of the series, was discovered as early as 1857 by Wurtz,[1] this material was merely a laboratory product until about 1925. There has been an extraordinary revival of interest in the glycols and their derivatives and these substances are finding numerous and important applications in chemical and other industries. The commercial development and large-scale production of the glycols, and especially of ethylene glycol, is undoubtedly due, in large measure, to the availability of large supplies of cheap ethylene (and its immediate homologues) as by-products in the cracking of higher petroleum fractions.

The conversion of olefins into glycols, which is exemplified by ethylene as follows:



$$\begin{matrix} CH_2 \\ \| \\ CH_2 \end{matrix} + H_2O + O \longrightarrow \begin{matrix} CH_2OH \\ | \\ CH_2OH \end{matrix}$$

is an oxidation process. Although the earlier workers in this field of synthesis (as well as the later commercial processes) employed intermediate compounds, such as the dihalides or chlorohydrins, to effect this conversion, attempts have been made to convert olefins directly into glycols by the action of oxidizing agents (Chapter 39). The direct methods of adding two hydroxyl groups to the double bond involve the use of such oxidizing agents as dilute potassium permanganate and concentrated persulphuric acid (or Caro's acid, H_2SO_5) or of such catalysts as osmium tetroxide. The earliest direct oxidation of unsaturated compounds to glycols was accomplished by Tanatar,[2] who prepared a tartaric acid from fumaric acid by the use of dilute aqueous potassium permanganate. Somewhat later Saytzeff[3] showed that the same reagent could be used to convert oleic and elaidic acids to dihydroxystearic acid. The hydroxylation of crotonic and cinnamic acids (also with potassium permanganate) was effected by Fittig.[4] That this reagent might be employed to convert unsaturated hydrocarbons into glycols was first demonstrated by Wagner,[5] who prepared in this way the glycols of ethylene, isopropylethylene, isobutylene and trimethylethylene as well as glycerol from allyl alcohol and ethylglycerol from ethylvinylcarbinol. A number of other investigators[6] have shown that dilute potassium permanganate converts mesityl oxide, unsaturated acids, and terpene hydrocarbons into glycols.

A reagent mentioned above which has been used with success to add two hydroxyls to the double bond is persulphuric acid or its primary decomposition product, Caro's acid. With this latter reagent Albitzsky[7] prepared dihydroxystearic acid from oleic and elaidic acids. Swann[8] converted allyl alcohol into glycerol and cyclohexene into trans-1,2-cyclohexanediol by the action of dilute aqueous solutions of persulphuric acid.

Another method of hydroxylating double bonds was discovered by Hofmann, Ehrhart and Schneider,[9] who succeeded in oxidizing ethylene to glycol and allyl alcohol to glycerol by the action of osmium tetroxide in the presence of an oxidizing agent (potassium chlorate). The method was improved for the oxidation of fumaric or maleic acids to tartaric acid by Milas and Terry.[10]

PRODUCTION OF ETHYLENE GLYCOL

Ethylene glycol was first prepared by Wurtz[11] from ethylene dibromide by reaction with anhydrous sodium acetate. The glycol diacetate thus formed was subsequently hydrolyzed to glycol. For the large-scale production of ethylene glycol two principal processes have been used industrially, namely, (1) the hydrolysis of ethylene dichloride, and (2) the hydrolysis of ethylene chlorohydrin. Another procedure involves the production of ethylene oxide from chlorohydrin, followed by hydration of the oxide to the glycol. These processes are discussed separately in this chapter.

The hydrolysis of ethylene dichloride takes place in the presence of alkalies, such as sodium carbonate, with the production of glycol but, unless conditions are carefully adjusted, the formation of other products, such as vinyl chloride, also occurs. With strong alkalies, vinyl chloride and acetylene result, and heating with water and lead oxide leads to the formation of glycol and aldehyde.[12]

Brooks and Humphrey[13] showed that conversion of the dichloride to glycol proceeds readily when the dichloride is heated under pressure with an alkali formate, ethylene diformate being an intermediate product. The process is carried out[14] by heating the dichloride with 1.25 to 2 times the theoretical amount of sodium formate in 3 to 5 volumes of methyl alcohol to 180° C. in an autoclave under a pressure of 260 pounds per square inch. At the end of the reaction, the liquid mixture is filtered to remove salt and then distilled first under ordinary pressure to remove methyl alcohol and methyl formate and then *in vacuo* to recover glycol.

Matter[15] proposed to hydrolyze ethylene dichloride by heating it in a closed vessel with an aqueous alkali bicarbonate solution in the presence of sheet copper as a catalyst. For example, 100 parts by weight of ethylene dichloride are heated with a solution of 180 parts of sodium bicarbonate in 1900 parts of water in a closed vessel during 6 hours at 130° to 140° C., the liquid being stirred continuously and a sheet of copper being used as catalyst. After cooling, the liquid is neutralized (e.g., with hydrochloric acid), concentrated, and fractionally distilled. In this way about 50 to 55 parts by weight of glycol are obtained.

According to Engelhardt[16] ethylene glycol is produced by heating ethylene dihalides with concentrated aqueous solutions of salts having a feebly alkaline reaction, such as sodium, potassium, or calcium acetate, potassium oxalate, sodium phosphate or potassium benzenesulphonate. Neutralizing agents (sodium or potassium carbonate) can be added continuously or intermittently to maintain the solution slightly alkaline. Hibbert[17] proposed to make glycols by heating the olefin dichloride with an aqueous solution of sodium carbonate at 150° to 200° C. in an apparatus capable of withstanding considerable pressure.

Hydrolysis of dichlorides with aqueous solutions of the calcium salt of a weak acid under pressure at temperatures of 100° to 150° C. in a closed vessel has also been suggested. The use of calcium carbonate for this purpose has been recommended by McElroy.[18] When the calcium salts of acetic, lactic, butyric, formic and tartaric acids are employed, the corresponding glycol esters are produced.

The production of mixed glycols from mixed olefin dichlorides by this process can be carried out as follows: The dichlorides are mixed with an equal amount of finely powdered calcium carbonate and enough water to render the mass pasty. The mixture is heated to 115° to 130° C. for 2 to 3 hours in a closed container fitted with agitators. The glycols are recovered from the reaction product by steaming out in a manner analogous to that used for the recovery of glycerol. By heating 100 parts of dichloride with 180 to 190 parts of commercial calcium acetate and 350 to 500 parts of water to 120° to 150° C. for 3 to 4 hours, glycol diacetate is obtained. With 90 parts of calcium acetate, 50 parts of calcium carbonate and 100 parts of dichloride, the monoacetate of the glycol results.

In the process of Rodebush,[19] ethylene glycol is produced by heating 10 parts of ethylene dichloride, 10 parts of sodium carbonate, 2 parts of sodium acetate, and 15 parts of ethyl alcohol at 150° C. under 175 pounds per square inch pressure in the presence of excess of water. Britton[20] used ethylene chlorobromide as an intermediate in the production of the glycol. Approximately 2 parts by weight of ethylene chlorobromide and 3 parts of sodium carbonate were heated in a closed container with 29 parts of water at 145° C. for 4 hours. An almost theoretical yield of the glycol, based on the chlorobromide decomposed, was said to result.

Maier[21] made ethylene glycol by saponification of the dichloride with water at temperatures above 120° C. under pressure, the hydrochloric acid formed being neutralized by the continuous addition of an alkali or an appropriate metallic oxide. At the end of the reaction, most of the water was distilled off, and the glycol was extracted from the residue with alcohol. In another procedure Maier[22] converted the olefin dihalide into an organic ester (the diacetate), which is subsequently hydrolyzed by excess water under pressure at temperatures above its boiling point.

The production of glycol-glycerol mixtures was effected by Schlegel, Arnold, Arnold and Arnold[23] by reaction of ethylene dichloride with spent lyes from the manufacture of soap, the alkali content of the lye having been first converted into carbonate or bicarbonate by carbon dioxide evolved in a previous hydrolysis.

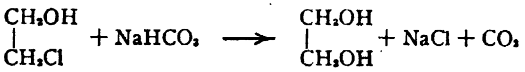
It has been known since 1873 that the olefin dihalides can be slowly hydrolyzed by water alone, but the reaction requires temperatures of the order of 170° C., or long periods of time at lower temperatures.[24] Bahr and Zieler[25] studied the hydrolysis of ethylene dichloride by water alone at various temperatures. Titration of the samples after heating for 1 hour gave the following conversions into glycol: at 160° C., 8 per cent; at 170° C., 18 per cent; and at 180° C., 34 per cent. The conversions obtained at various time intervals at 170° C. and 180° C., respectively, are given in Table 104.

Table 104.—*Hydrolysis of Ethylene Dibromide to Glycol.*

Time in Hours	At 170° C.	At 180° C.
	Per Cent	
0.5	8	—
0.75	—	31
1.0	18	34
1.5	—	41
2.0	28	—
2.5	—	61

It was shown that aldehydes began to be formed in quantity if the hydrochloric acid content of the liquid exceeded 1 per cent. A method of autoclave treatment was therefore adopted, which included addition of alkali at intervals to neutralize the excess hydrochloric acid. At 150° to 170° C., yields of 70 per cent were obtained with only small amounts of aldehyde or vinyl chloride. A loss of 20 to 25 per cent was attributed to volatilization or resinification of aldehyde. On a larger scale a yield of 1.5 to 2.0 kilograms of glycol per hour per 100 liters of reacting liquid resulted with a mixture containing 4 to 5 per cent of ethylene dichloride.

A number of processes use ethylene chlorohydrin as the starting material for the manufacture of glycol. The hydrolysis of ethylene chlorohydrin is effected, for the most part, with aqueous solutions of weak alkalies, such as sodium bicarbonate, according to the reaction:



$$\begin{matrix} CH_2OH \\ | \\ CH_2Cl \end{matrix} + NaHCO_3 \longrightarrow \begin{matrix} CH_2OH \\ | \\ CH_2OH \end{matrix} + NaCl + CO_2$$

The use of anhydrous caustic alkalies results in the formation of olefin oxides, whereas more dilute caustic alkalies promote the formation of tarry non-distillable materials. Brooks[26] stated that when aqueous solutions of ethylene or propylene chlorohydrins are heated with aqueous sodium bicarbonate solutions, marked evolution of carbon dioxide ensues at about 65° C. By refluxing with sodium carbonate or bicarbonate solutions, yields of glycol are 44 to 48 per cent of the theoretical, the remainder being converted into olefin oxides which, on account of their volatility, are lost. By carrying out the reaction in a closed autoclave at 105° to 110° C. for 2 hours, yields of glycol of 90 per cent may be obtained. The remaining 10 per cent is converted into tarry material which cannot be distilled without decomposition, even under 10 mm. pressure. Calcium or magnesium hydroxides are not satisfactory for the hydrolysis as they firmly retain the glycol.

---

[24] Eltekow, *Ber.*, 1873, 6, 158; *Chem. Soc. Abs.*, 1873, 26, 1016.
[25] *Z. angew. Chem.*, 1930, 43, 286; *Chem. Abs.*, 1930, 24, 3213.
[26] *Chem. Met. Eng.*, 1920, 22, 631.

The hydrolysis of ethylene chlorohydrin to produce glycol was described by Curme and Young.[27] A solution of caustic soda (about 20 per cent NaOH) is introduced into a kettle, and carbon dioxide is admitted in the cold, thus producing a solution of sodium bicarbonate. When the sodium hydroxide has been converted into bicarbonate, a charge of chlorohydrin solution (containing the precise amount of chlorohydrin necessary for complete reaction with the bicarbonate) is added to the bicarbonate solution in the kettle. The temperature of the reacting liquid is raised to 70° to 80° C., stirring meanwhile, and the hydrolysis is completed in about 4 to 6 hours. A further quantity of sodium hydroxide equivalent to a second charge of chlorohydrin, is treated in a second kettle with carbon dioxide derived from the reaction in the first. The carbon dioxide liberated entrains a considerable quantity of chlorohydrin which is thus wholly recovered by the absorption of gas in the caustic solution for the next operation. The reaction mixture is heated until evolution of carbon dioxide ceases and the charge is then withdrawn and a further quantity of caustic soda solution introduced while a new charge of chlorohydrin solution is added to the bicarbonate in the second kettle, and the process proceeds as before. It is stated that it is best to employ a 40 per cent chlorohydrin solution and to regulate the concentration of the alkali so that the actual chlorohydrin concentration in the reaction liquid at the beginning of the hydrolysis approximates 20 per cent.

Later, Curme[28] proposed to hydrolyze chlorohydrins with a solution of caustic alkali under such conditions that any appreciable escape of the intermediate olefin oxide is prevented, e.g., by using a vessel completely filled with liquid. The process may be made continuous. Calcium carbonate or a solution of calcium bicarbonate has been suggested by Oehme[29] for the hydrolysis of ethylene chlorohydrin.

Saunders and Wignall[30] described a continuous process for the vapor-phase hydrolysis of ethylene chlorohydrin to glycol or ethylene oxide by a solution of sodium carbonate or sodium hydroxide. At the bottom of a scrubber tower, lagged and filled with packing, a steady stream of steam enters and ascends against a descending flow of crude weak chlorohydrin solution. The amount of steam is adjusted so that it is exactly sufficient to volatilize and carry upwards the ethylene chlorohydrin contained in the solution. The current of steam laden with chlorohydrin traverses a fractionating column and passes away at the top, carrying 95 per cent of the chlorohydrin contained in the crude solution. The vapor then passes down a well-lagged pipe to the bottom of a second packed tower, which it enters by bubbling through hot liquid at the bottom. The admixed ethylene chlorohydrin vapors and steam ascending this tower meet a down-flowing solution of sodium carbonate (if ethylene glycol as such is to be obtained) or of caustic soda (if ethylene oxide is desired) admitted in the correct proportion. The ethylene chlorohydrin is hydrolyzed to the glycol with concomitant production of salt (NaCl), while steam, carbon dioxide, and volatile unhydrolyzable impurities pass away to a first condenser. The ethylene glycol dissolves in the salt solution and is carried down to the bottom of the tower and then flows from the trap direct to a desalter. The water and oily impurities are collected in a catch-pot where they form two layers. The oil is drawn off at the bottom and the water overflows at the top into the gas-separator. When ethylene oxide is formed it passes away at the top of the tower and can be dried and collected.

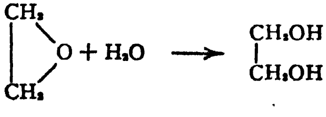
[30] U. S. Patent 1,737,545, Nov. 26, 1929; British Patent 286,850, 1927; *Chem. Abs.*, 1929, **23**, 397; both patents assigned to British Dyestuffs Corp., Ltd.

Another method for the production of glycols direct from olefins such as ethylene, propylene, or aryl-substituted alkylenes (e.g., styrene) is described by Essex and Ward.[31] The olefin is introduced, together with carbon dioxide, into a cold 5 per cent sodium hypochlorite solution. The resulting chlorohydrin solution is then heated under a reflux condenser for several hours to obtain the glycol. In this manner ethylene glycol can be obtained from ethylene; phenylglycol, from styrene; and glycerol, from allyl alcohol. The production of glycols with sodium hypochlorite has also been described by Blanchet.[32]

Dunstan and Birch[33] proposed a process for the manufacture of ethylene glycol in which an aqueous solution of ethylene chlorohydrin is mixed continuously with an aqueous solution of a non-caustic alkali (e.g., sodium carbonate) and heated to 105° to 150° C. under pressure. The hot reaction mixture is allowed to flow, under pressure at reaction temperature, through a series of heated "U" tubes, the rear limbs of which are packed and the forward limbs provided with downward-sloping baffles.

A method for the extraction of ethylene glycol or its homologues from aqueous solutions containing calcium or magnesium chlorides (such as are obtained in the hydrolysis of chlorohydrins by aqueous solutions or suspensions of lime or magnesia) is described by Oehme.[34] The mixture is distilled *in vacuo* at 250° to 400° C. with continuous stirring, or the liquid may be passed, after preliminary evaporation, through a tubular vacuum evaporator with a final temperature of 280° to 320° C. Anhydrous calcium (or magnesium) chloride is recovered and the distillate, containing 25 to 35 per cent of glycol, is further rectified.

Closely allied with the above processes are those which involve the hydration of ethylene oxide, previously prepared from ethylene chlorohydrin, e.g., by treatment with anhydrous (or concentrated aqueous) alkali. The conversion of ethylene oxide into glycol by hydrolysis with water is easily carried out by heating in a closed vessel.[35] The reaction is accelerated by the addition of mineral acids, especially sulphuric acid.[36] In large-scale practice, the considerable heat evolution (about 25 kg. cals. per mole) must be considered. It has been proposed to effect the hydration of ethylene oxide according to the reaction



$$\begin{matrix} CH_2 \\ | \quad \diagdown \\ | \quad\; O \\ | \quad \diagup \\ CH_2 \end{matrix} + H_2O \longrightarrow \begin{matrix} CH_2OH \\ | \\ CH_2OH \end{matrix}$$

in the presence of dilute sulphuric acid as a catalyst.[37]

According to Youtz,[38] glycols may be obtained by mixing olefin oxides with excess of water (20 molar proportions of the latter to one of olefin oxide) and a hydrolyzing catalyst and then heating above the boiling point of the olefin oxide. The use of a large excess of water is said to suppress the simultaneous formation of polyglycols.

Attention has already been directed to the possibility of directly oxidizing ethylene in the presence of water to yield ethylene glycol (see also Chapter 39). Skärblom[39] proposed to manufacture ethylene glycol from ethylene by introducing a mixture of ethylene and oxygen into water containing iodine (or a compound of iodine in which the iodine is combined sufficiently loosely to react with the ethylene in the presence of oxygen, for example, hydrogen iodide, ethylene diiodide, potassium triiodide or ferric triiodide). The reaction is carried out in the presence of a salt of iron or manganese or other oxidation catalyst. A similar method[39a] for preparing ethylene glycol consists in reacting air and water with ethylene at 150° to 300° C. under pressure, using antimony, lead, bismuth, silver, nickel, tin or arsenic as catalysts.

Electrolysis of an alkali metal hydroxide solution of an olefin under pressures of about 20 to 200 atmospheres has been proposed by Youtz[40] for the production of glycol. Hydrogenation of lactones also yields glycols.[40a]

CHEMICAL AND PHYSICAL PROPERTIES OF ETHYLENE GLYCOL

Ethylene glycol is a colorless, odorless liquid with a sweet taste. It melts[41] between —17.4° C. and —11.5° C. (indefinite because of tendency to supercool[42]), boils at 197.5° C. at 760 mm., and has a density of 1.115 at 20° C. It is miscible in all proportions with water, alcohol and many organic solvents, and 100 parts of ethyl ether dissolve 1.1 parts of glycol. Although in its general physical properties it bears a striking resemblance to glycerol on one hand and ethyl alcohol on the other, it differs from them in several particulars. Thus, for example, it is less viscous than glycerol and can be distilled without decomposition at atmospheric pressure.[43] In the anhydrous state it is exceedingly hygroscopic. There is some evidence for the existence of a dihydrate.[44]

The chemical properties of this glycol are those expected of a dihydric alcohol. Thus, it forms both mono- and di-esters which may be conveniently prepared from ethylene dichloride or chlorohydrin. A large number of ethers and ether-esters are also known, some of which are discussed more fully later. The ethers are conveniently produced by condensation of alcohols or phenols with ethylene oxide. Both mono- and di-metallic derivatives of glycol are known.[45]

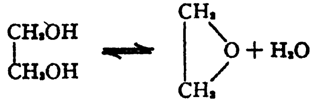
On dehydration, ethylene glycol yields ethylene oxide to some extent:

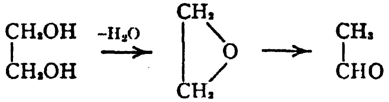


In this reaction, however, polyglycols are also produced depending upon the conditions. The formation of diethylene and triethylene glycols from ethylene glycol by elimination of water may be represented as follows:

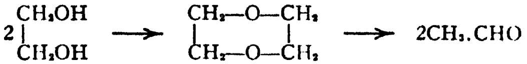
$$HOCH_2CH_2OH + HOCH_2CH_2OH \longrightarrow \underset{\textit{diethylene glycol}}{HOCH_2CH_2{-}O{-}CH_2CH_2OH} + H_2O$$

$$HOCH_2CH_2{-}O{-}CH_2CH_2OH + HOCH_2CH_2OH$$
$$\longrightarrow \underset{\textit{triethylene glycol}}{HOCH_2CH_2{-}O{-}CH_2CH_2{-}O{-}CH_2CH_2OH} + H_2O$$

In the presence of dilute mineral acids at fairly high temperatures (200° to 210° C.) ethylene glycol undergoes dehydration with the production of acetaldehyde, as well as other substances.[46] In this reaction Baeyer and Erlenmeyer[47] both assumed the intermediate formation of an unsaturated alcohol which was isomerized to acetaldehyde. Krassuski[48] believed that ethylene oxide was the intermediate compound thus:



On the other hand, Favorsky,[49] by distilling glycol with 4 per cent concentrated sulphuric acid, obtained mainly dioxan with acetaldehyde and glycol acetal. Distillation of dioxan with dilute sulphuric acid was found to yield some acetaldehyde and acetal and, therefore, Favorsky assumed that the reaction proceeded through the intermediate formation of dioxan, thus:



In a similar way, propylene glycol when heated to 220° C. with very small amounts of hydrochloric acid, yielded propionaldehyde mainly.[50]

A considerable number of cyclic acetals (or cyclic diethers) of ethylene glycol are known. A methylal of ethylene glycol was prepared by Trillat and Cambier[51] by gently heating equimolecular quantities of trioxymethylene and ethylene glycol with 2 per cent ferric chloride. This substance, which was subsequently shown by Henry[52] to have the structure:

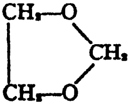
[52] *Compt. rend.*, 1895, 120, 107; *Chem. Soc. Abs.*, 1895, 68 (1), 266.

is a liquid boiling at 74°-75° C. It can also be prepared by heating together 100 grams of glycol, 50 grams of 40 per cent formaldehyde solution, and 50 grams of syrupy phosphoric acid. In the same way, acetaldehyde and glycol yield an acetal boiling at 82° C. and isobutyraldehyde forms an acetal which boils at 122° C.[53] Cyclic diethers can be obtained by the reaction of glycols with an aqueous solution containing equimolecular quantities of water and an aldehyde or ketone in the presence of sulphuric acid at 140° C., according to Dreyfus.[53a]

Cyclic acetals are also obtainable by condensing glycol with butyraldehyde[54] and crotonaldehyde,[55] and also by condensing acetylene with glycol in the presence of mercuric sulphate.[56] In the latter, acetaldehyde is apparently the intermediate compound which immediately condenses with the glycol.

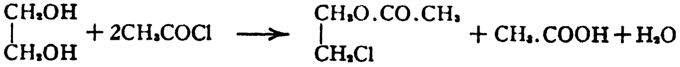
A method of producing cyclic ethers of glycols consists in the reaction of halogenated ethers with metallic oxides. Thus, the cyclic acetal,



may be prepared from chloromethyl-β-chloroethyl ether and copper oxide.[57] Various cyclic acetals obtained by condensing phenylated aliphatic aldehydes with 1,2-glycols are said to be usable in the preparation of perfumes. Among these may be mentioned the cyclic acetal from phenylacetaldehyde and ethylene glycol, which has a rose-like odor.[58]

The decomposition of ethylene glycol in the presence of vanadium pentoxide has been studied by Drake and Smith.[59] At 250° to 400° C. the main decomposition products are acetaldehyde and ethylene but small amounts of oxides of carbon and acetic acid are also formed. At temperatures up to about 320° C., ethylene is the major product. The minimum amount of ethylene results at about 360° C., at which temperature aldehyde formation is at a maximum.

Ethylene glycol, containing two hydroxyl groups, reacts with phosphorus pentachloride yielding ethylene dichloride.[60] With organic acid chlorides the 1,2-glycols react with the formation of acyl derivatives of the corresponding chlorohydrins.[61] In the case of ethylene glycol and acetyl chloride this reaction can be represented as:



$$\begin{matrix} CH_2OH \\ | \\ CH_2OH \end{matrix} + 2CH_3COCl \longrightarrow \begin{matrix} CH_2O.CO.CH_3 \\ | \\ CH_2Cl \end{matrix} + CH_3.COOH + H_2O$$

On treatment with concentrated hydrochloric acid at 148° to 160° C. ethylene glycol is partly converted into the chlorohydrin,[62] but at 200° C. (or at lower temperatures in the presence of hydrogen chloride), ethylene dichloride is formed.[63]

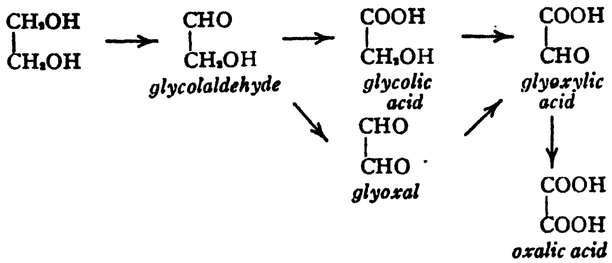
On oxidation (with nitric acid or alkaline lead peroxide) ethylene glycol is converted into one or more products,[64] the various steps being represented as follows:



Because of its solvent action, which approximates that of ethyl alcohol for certain substances, ethylene glycol has found some application in the preparation of flavoring extracts. The toxicity of ethylene glycol toward dogs, rabbits, and rats was studied by Page[65] who compared its effects with those of glucose and glycerol. Injected intravenously, it quickly lowered the blood pressure. Tests on rabbits by Fuller[66] showed that 5 to 10 cc. doses administered daily in 50 per cent aqueous solution produced no pathological symptoms. Daily doses of 15 to 20 cc. in 50 per cent aqueous solution were attended with no outward symptoms but autopsies revealed evidence of chronic gastritis. Since these doses are, however, far in excess of what would be absorbed by a human being in a food product, Fuller concluded that ethylene glycol could be safely used in such materials.

Experiments on its inhibitory and disinfectant action toward *Bacillus typhosus* (Rawlings), a wine yeast and a mixed mold culture indicated that its value in this respect lies between that of glycerol and ethyl alcohol and does not fall far short of the latter. In direct opposition to Fuller's conclusions, Hunt[67] stated that ethylene glycol is as poisonous as methanol and that its toxicity is to be attributed to oxalic acid which is formed by oxidation in the body. Hunt's statements have been contested by Hanzlik[68] but, in reply, Hunt[69] cited additional evidence in support of his contention. The use of ethylene glycol in food products, according to Hunt, is to be deprecated, although there is no objection to its application in certain medicinal preparations. Two serious cases of ethylene glycol poisoning were reported by Brekke,[70] the initial symptoms being similar to alcohol intoxication, followed later by paralysis of some of the cerebral nerves and hemorrhagic nephritis. The irritant and toxic properties of ethylene glycol have been investigated by Hanzlik, Seidenfeld and Johnson,[71] and the relation between the pharmacological action and the chemical constitution of ethylene glycol derivatives have been discussed by von Oettingen and Jirouch.[72]

Applications of Ethylene Glycol

Ethylene glycol has found use in the preparation of glycol dinitrate, as an anti-freeze for automobile radiators, and as a solvent and preservative in food products and medicines. The properties and applications of glycol dinitrate are described later.

The use of ethylene glycol as an anti-freeze in automobile radiators is largely the result of efforts of the Carbide and Carbon Chemicals Corporation,[73] who marketed this material under the trade name of "Prestone". The specifications of an ideal anti-freeze solution, as drawn up by the U. S. Bureau of Standards,[74] are as follows:

The material shall prevent freezing of the radiator liquid without injuring engine or radiator. The non-freezing properties of the solution should, moreover, be permanent and not reduced on continued use. Furthermore, the material should not materially change the boiling point of water when dissolved in it.

To the above specifications, might advantageously be added: The material should be odorless, non-inflammable, non-corrosive, and should not attack automobile finishes and its aqueous solutions should possess a high heat capacity and a low vicosity.[75]

Of the other materials which have been proposed for anti-freeze solutions, ethyl alcohol and glycerol have found extensive application. Ethylene glycol fulfills the requirements of an anti-freeze. In aqueous solution it depresses the freezing point in proportion to the concentration present, down to about 60 per cent by volume, which solution freezes at —49° C. (—56° F.). For higher concentrations of glycol, the freezing point increases again to —11.6° C. (11.3° F.), that of pure glycol. The use of 1,2-glycols, particularly ethylene glycol, in aqueous solution as anti-freeze liquids in automobile cooling systems was described by Hibbert.[76] Mixtures containing 60 to 65 parts of water and 35 to 40 parts of 1,2-glycols are particularly satisfactory for this purpose.

As a solvent,[76a] ethylene glycol has many of the characteristics of ethyl alcohol. It dissolves esters, medicaments, resins, flavors, and dyes. The use of ethylene glycol as a solvent in the manufacture of concentrated fruit flavors, flavoring extracts and similar commodities has been discussed by Fuller[77] and Smith and Eoff.[78]

The combined preservative and hygroscopic nature of ethylene glycol recommend it for a wide variety of applications, especially in the manufacture of cosmetics, in the preparation of anatomical and biological specimens, in the treatment of skin and furs, in the moistening of tobacco, as a means of preserving the suppleness and flexibility of leather during processing, and in the textile industry as an aid to the finishing and dyeing of fabrics.[79] According to McElroy[80] a good hygroscopic composition for incorporation in medicinal products consists of ethylene glycol, water, and a water-soluble substance such as cane sugar, invert sugar, lactose, calcium chloride or boric acid.

The use of ethylene glycol as a substitute for glycerol in some of its applications has been described by Braun[81] and its employment in the grading of collodion membranes has been investigated by Field and Thomas.[82]

Numerous derivatives of ethylene glycol, such as esters and ethers, are finding important applications in the chemical industry. With the exception of the dinitrate, most of these materials are being manufactured from either the olefin dichloride or the chlorohydrin. Synthetic resins have been produced, for example, by condensation of ethylene glycol with phthalic anhydride.[83] Ethylene glycol has been used in liquid media for heat-transfer[84] and as an absorption liquid for methylamine in refrigeration.[85] In the manufacture of beeswax candles,[86] sticking to the molds is said to be prevented by the incorporation of 5 per cent of the glycol. A selective solvent prepared by mixing a glycol with phenol has been proposed by Stratford[86a] for removing impurities from kerosene or lubricating oils. Thomas and Hochwalt[86b] used a solution of sodium potassium carbonate in ethylene glycol and water as an anti-freeze charge for carbonate-sulphuric acid fire extinguishers. Reddish blue dyestuffs have been obtained by condensing ethylene glycol with halogenated dibenzanthrones, containing at least two halogen atoms.[87]

ETHYLENE GLYCOL DINITRATE

Henry[88] was the first to prepare and identify glycol dinitrate. This compound was made by dropping small portions of the glycol into a mixture of sulphuric and nitric acids cooled to 0° C. Previously, however, Kekulé[89] had obtained a mixture of the glycol dinitrate and the nitric ester of β-nitroethanol[90] ($CH_2(O.NO_2)CH_2NO_2$) by the nitration of ethylene. Champion[91] prepared the dinitrate by solution of 42 grams of glycol in a mixture of 100 grams of fuming nitric acid and 200 grams of 66° Bé sulphuric acid, and Nef[92] used 10 cc. of the glycol with a mixture of 20 cc. of nitric acid (specific gravity, 1.52) and 40 cc. of sulphuric acid (specific gravity, 1.8), cooled to —10° to —15° C. The method employed by Rinkenbach[93] consisted in slowly adding 20 grams of purified glycol[94] to a mixture of 70 grams of nitric acid (specific gravity, 1.42) and 130 grams of sulphuric acid (specific gravity, 1.84) at a temperature of

23° C. The crude dinitrate (49 grams) separated and after washing with 300 cc. of water in small portions, a yield of 39.6 grams of acid-free material resulted. The low yield can be improved by maintaining a lower temperature and by using a different nitrating acid mixture. The product obtained possessed a nitrogen content of 18.37 per cent (theoretical, 18.43 per cent).

According to Rinkenbach, pure ethylene glycol dinitrate is a colorless, neutral, mobile liquid at ordinary temperatures, with a peculiar sweetish taste and no appreciable odor. Its physical properties are as follows: D^{0}_{15} 1.5176; D^{15}_{15} 1.4962; D^{25}_{15} 1.4817; freezing point, —22.3° C.; heat of fusion, 30.0 cal. per g.; heat of combustion, 268.22 kg.-cal. (constant volume) or 266.48 kg.-cal. (constant pressure) per mole; n^{0}_{D} 1.4546; n^{15}_{D} 1.4491; n^{30}_{D} 1.4436; heat of formation, 365.5 cal. per g.; vapor pressure at 0° C., 0.0072 mm. and at 22° C., 0.0565 mm. (Rinkenbach) or 0.0465 mm. (Crater[95]).

Various other methods for the preparation of the dinitrate alone or in admixture for use in explosives have also been devised.[96] Among these are procedures which deal with the production of the dinitrate by nitration of glycol or ethylene oxide,[97] of sulphoglycol,[98] of mixtures of glycols,[99] of ethylene,[100] and of the condensation products of glycol with 3,4-dinitrochlorobenzene.[101] Hough[102] proposed to mix the dinitrate with nitroglycerol and Matthews, Strange and Bliss[103] described explosives containing nitrated 1,2-glycols, nitroglycerol and infusorial earth. Explosives containing nitroglycerol with nitrocellulose and nitrate salts[104] are said to have been manufactured industrially in Europe.[105] Several explosives containing nitrated 1,2-glycols were suggested by Barab,[106] who has also recommended propylene glycol dinitrate[107] for this purpose.

The great value of glycol dinitrates in explosives lies in their low freezing point and their capacity to form low freezing mixtures with nitroglycerol. They possess lower sensitivity to shock and greater fluidity than nitroglycerol, together with perfect oxygen balance and they are practically non-hygroscopic. About 9 million pounds of ethylene glycol were employed in the manufacture of low-freezing dynamites in the United States in 1927.[108]

The physiological action of glycol dinitrate is similar to that of nitroglycerol but because of its higher vapor pressure (approximately 150 times greater than that of glyceryl trinitrate at 22° C.) the inhalation of sufficient vapor to cause injurious effects is more likely to occur. This high volatility is one objection to the use of glycol dinitrates.[109] Because of the toxicity of the volatile dinitrate, Schmid[110] recommended a continuous nitration process for its manufacture. Gelatinization of nitrocotton is effected more quickly by glycol dinitrate than by nitroglycerol so that a slow-gelatinizing nitrocotton must be used, or uneven results are obtained. Homogeneous transparent "gelatins" were prepared by Schmid by gelatinization at 0° to 1.5° C. Compared with the gelatins obtained from nitroglycerol, those from glycol dinitrate are stickier and not so stiff, but this disadvantage is overcome by the use of larger amounts of nitrocotton and absorbent.

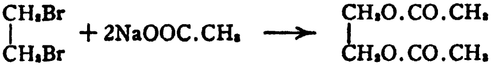
ETHYLENE GLYCOL ACETATES

Both mono- and di-esters of the glycols are known, the methods for their technical production being:

(1) Reaction of ethylene dihalide (especially dichloride) with salts of fatty acids.
(2) Esterification of glycols with fatty acids or their anhydrides.
(3) Condensation of olefin oxides with fatty acids or their anhydrides.

The reaction of ethylene dihalides with salts of organic acids appears to be a fairly general method for the preparation of glycol esters. Depending upon the relative proportions of the reactants, either the mono- or di-esters may be formed. Thus, Atkinson[111] obtained glycol monoacetate by heating the dibromide with potassium acetate in 85 per cent alcohol. Henry[112] heated 570 grams of ethylene dibromide and 300 grams of anhydrous potassium acetate with the addition of a little acetic anhydride for 10 hours and obtained an almost quantitative yield of the diacetate:



$$\begin{matrix} CH_2Br \\ | \\ CH_2Br \end{matrix} + 2NaOOC.CH_3 \longrightarrow \begin{matrix} CH_2O.CO.CH_3 \\ | \\ CH_2O.CO.CH_3 \end{matrix}$$

Drushel and Bancroft[113] boiled 300 grams of the dibromide with 155 grams of fused potassium acetate in 300 grams of 85 per cent alcohol for 18 hours and obtained 83 grams of diacetate, but no monoacetate.

From a technical standpoint, it is far too expensive to employ bromides and potassium salts for the production of glycol esters. Good results have been achieved with ethylene dichloride and the sodium salts of organic acids. For example, glycol diacetate may be readily prepared from ethylene dichloride and anhydrous sodium acetate.[114] According to Rodebush,[115] glycol esters are made by heating a mixture of ethylene dichloride, fused potassium, sodium, calcium, or magnesium acetates, and alcohol to 180° C. under pressure for 1 hour. The method is applicable to the preparation of numerous esters of ethylene glycol, including the salicylate[116] and stearate.[117] The commercial preparation of glycol diacetate is described as follows by Killeffer.[118] One mole of ethylene dichloride, slightly more than two moles of anhydrous sodium acetate (or better, 5 per cent in excess of this) and 2 to 3 per cent of glycol diacetate, are mixed, stirred, and heated in an autoclave at pressures of 125 to 150 pounds per square inch until the pressure drops, indicating that all the volatile dichloride is consumed. The product is then distilled off.

The second general method of preparation of glycol esters was employed by

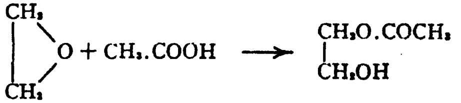
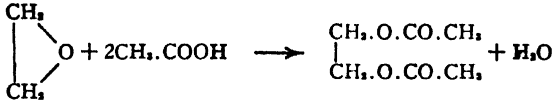
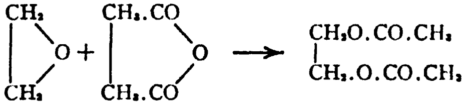
Drushel and Bancroft[119] to make the monoacetate of ethylene glycol by heating equimolecular quantities of glacial acetic acid and the glycol with anhydrous copper sulphate. According to Watson,[120] either the mono- or di-esters of the glycols may be obtained, depending upon the proportions of the reactants. To obviate the use of catalysts, such as sulphuric acid, which promote undesirable side reactions, the water formed in the reaction can be removed by continuous distillation during the esterification. In making ethylene glycol monoacetate, for example, commercial glycol is refluxed with a little more than the stoichiometric quantity of commercial 28 per cent acetic acid, allowing water vapors to escape and returning acid and glycol back to the reaction mixture. When the acidity has been reduced to the extent required, the residual acid is distilled off and the crude ester fractionated. In the production of the diacetate, the procedure is the same except, of course, that twice the quantity of acid is added. The process is applicable to the production of di- and mono-formates, valerates, oleates, stearates, and other esters.

The third method for making esters of glycols consists in the condensation of an olefin oxide with an anhydrous organic acid, often in the presence of a condensing agent. By this method, Wurtz[121] obtained both the mono- and diacetates of ethylene glycol according to the reactions:





Condensation of ethylene oxide with glacial acetic acid yields a mixture of the mono- and di-acetates, and it has been observed that anhydrous ferric chloride facilitates the esterification.[122] On the other hand, condensation of ethylene oxide with acetic anhydride (or other acid anhydrides) yields the di-ester exclusively:



Inorganic acids (sulphuric acid) or an acid salt (sodium bisulphate) or a salt of a strong base with an organic acid other than that to be esterified, have been suggested for condensing olefin oxides with organic acids.[123] In another process[124] the reaction between alkylene oxides and carboxylic acids is catalyzed by an acidulated aluminum hydrosilicate in which the hydrogen-ion concentration produced by suspension of the catalyst in water corresponds to a p_H value of less than 3.

Ethylene glycol monoacetate (boiling point, 181° C.) can be used as a solvent, especially for various synthetic resins derived from urea-formaldehyde condensations.[125] On account of the presence of a free hydroxyl group it is a water-soluble solvent. Ethylene glycol diacetate (boiling point, 186° C.) is a solvent for both cellulose acetate and nitrate as well as for certain resins. It possesses a slight odor similar to that of ethyl acetate, but rather less pronounced, and has been suggested as a solvent for flavors and as a fixative in perfumery.[126] Glycol monoacetate is said to be a satisfactory solvent for the deresination of crude montan wax.[127] Both the mono- and di-acetates can be used for removing free fatty acids from oils or fats.[128]

Many other mono- and di-esters of ethylene glycol are known but they do not appear to be of industrial importance. Ethylene glycol monobenzoate is a solid melting at 45° C., which can be dissolved in almost any proportions in solutions of the alkali salts of benzoic, toluic, and salicylic acids.[129] The monochloroacetic ester of ethylene glycol has been proposed as a denaturant for alcohol.[130] The glycol diester of monochloroacetic acid has been recommended as an insecticide, fungicide and disinfectant when diluted with kerosene.[131]

GLYCOL ESTERS OF DICARBOXYLIC ACIDS

The esters of the glycols with dibasic acids polymerize readily, very few of them being known in the monomeric condition.[132] Monomeric ethylene glycol oxalate is a crystalline solid (melting point, 143° C.) which, on standing for a few days in a stoppered bottle, is spontaneously transformed into a powder consisting of a mixture of polymers. By extraction with cold solvents this polymerized product can be separated into two fractions, one melting at 159° C. and having an apparent molecular weight of about 3000, and another melting at 173° C., which probably has a much higher molecular weight. These fractions, on standing, are still further converted, part of them going to the monomer.

When ethylene glycol is heated with an equimolecular proportion of succinic, adipic, phthalic, or other dibasic acid, the products are highly polymerized esters. These polymerized esters are non-volatile, dissolve quite readily in cold chloroform, and probably consist of a mixture of substances of varying molecular weights. Despite their high molecular weights and lack of homogeneity, with the exception of the phthalates, they are micro-crystalline solids. The chemical constitution of these substances has been elucidated by Carothers and his co-workers, who have shown that they are open-chain molecules containing alternate links of glycol and acid radicals. Thus, the neutral glycol succinates possess the structure:

in which X may be as high as 22.

Besides the above neutral polyesters, acidic polyesters may also be prepared by esterifying the glycol with an excess of the dibasic acid. A number of acidic ethylene glycol succinates, with molecular weights varying from about 1000 to 3000, have been thus prepared.

A highly viscous, colorless liquid, soluble in water, is obtained by heating equimolecular proportions of ethylene oxide and powdered phthalic acid at 60° to 65° C.[133] The yield is 180 per cent of the weight of phthalic acid.

GLYCOL ETHERS

Both mono- and di-alkyl ethers of ethylene glycol are known, the former being by far the more important industrially. The monoalkyl ethers form esters with organic acids. Both the monoalkyl ethers and their esters are solvents. The monoalkyl derivatives of ethylene glycol may be produced industrially in several ways.

Monoalkyl derivatives can be prepared by reaction of an olefin oxide with an alcohol or a phenol, usually in the presence of a catalyst. For this purpose, sulphuric acid has been proposed.[134] Thus, by passing ethylene oxide slowly into methyl alcohol containing 1 per cent of sulphuric acid at 15° C., a 90 per cent yield of the monomethyl ether is produced. The monoethyl ether can be prepared similarly. Young [135] employed higher temperatures and pressures, rather than catalysts, to effect this reaction. For example, a mixture of ethylene oxide and ethyl alcohol heated in an autoclave at 150° C. for 12 hours (or at 200° C. for 3 to 4 hours) gave a 70 per cent yield of the monoethyl ether.

Gibson and Payman [136] proposed to manufacture glycol monoalkyl ethers by condensing ethylene oxide with an alcohol in the presence of normal sulphates of multivalent elements, such as nickel, zinc, or chromium. On heating 82 parts of ethylene oxide, 410 parts of methyl alcohol and 2 parts of zinc sulphate in an autoclave at 100° to 105° C. for 6 to 8 hours, 102 parts (75 per cent) of the monomethyl ether formed. Similarly, by heating 88 parts of ethylene oxide with 440 parts of ethyl alcohol and 2 parts of nickel sulphate in an autoclave at 100° C., 126 parts of the monoethyl ether were obtained, a yield of 70 per cent of the theoretical.

Primary, secondary, and tertiary alcohols may be converted into their hydroxyalkyl ethers by reaction with olefin oxides in the presence of catalysts consisting of acidulated hydrosilicates, especially those of aluminum.[137] The hydrosilicates are activated by a preliminary acid treatment with an aqueous solution of a strong acid so that the resulting material, when dispersed in water, has a $p_{\rm H}$ value between 1.5 and 3.0. A stream of ethylene oxide (98.6 parts), for example, introduced into a mixture of 500 parts of ethyl alcohol and 25 parts of "Tonsil AC" (with a p_H value in water of 2.3) at 79° to 82° C., produced ethylene glycol monoethyl ether in yields of over 80 per cent (calculated on the ethylene oxide used). In a similar way, ethylene glycol monomethyl ether (85 per cent yield) can be prepared from ethylene oxide and methanol; 1,2-propylene glycol monoethyl ether (85 per cent yield), from 1,2-propylene oxide and ethyl alcohol; and butylene glycol monoethyl ether, from butylene oxides and ethyl alcohol.

[137] I. G. Farbenindustrie A.-G., British Patent 354,357, 1930; *Brit. Chem. Abs.* **B**, 1932, 12. The use of this catalyst for the reaction between alkylene oxides and organic acids has been mentioned in a preceding section.

A continuous process for the manufacture of glycol monoethers has been proposed,[138] in which a mixture of an olefin oxide and an organic hydroxy compound (in excess) is led continuously through a reaction vessel where the mixture is immediately heated to a temperature above 130° C., generally under pressures above 10 atmospheres. The advantages of such a process, in which catalysts are not employed, include rapid reaction with high production capacity, utilization of a considerable part of the heat of reaction to preheat fresh material, and development of relatively small pressures as a result of dilution of the volatile oxide by larger quantities of the second reactant. In practice, a mixture of 1 mole of ethylene oxide and 2 moles of ethyl alcohol is continuously pumped into a tower in which the liquid is immediately heated to 180° C., a pressure of 30 atmospheres being attained. The resulting solution is continuously fed to an open still, in which the solution is freed from excess alcohol. A theoretical yield of ethylene glycol monoethyl ether is said to be thus obtained. Similarly, an 85 per cent yield of ethylene glycol monophenyl ether may be produced by continuously pumping a mixture of 1 mole of ethylene oxide and 2 moles of phenol through a tower in which the mixture is rapidly heated to 200° C., the pressure developed being about 10 atmospheres.

In the process of Birch and Scott,[139] monoalkyl ethers of 1,2-glycols are produced by heating olefin oxides with alcohols under pressure in the presence of diethyl or dimethyl sulphate. Ethylene glycol monoethyl ether was formed in 90 to 95 per cent yield by heating ethylene oxide (30 volumes) and ethyl alcohol (300 volumes) at 100° C. under a pressure of 50 to 60 pounds per square inch with addition of a small amount (1 volume) of diethyl sulphate.

The condensation of alkylene oxides with hydroxy compounds is not limited to the simple monohydric alcohols, but may be applied to polyhydroxy compounds such as carbohydrates or polyvinyl alcohol.[140] Combination can be effected in alkaline aqueous media, even at room temperature, and the products are hydroxyalkyl ethers. For example, a polyvinyl alcohol treated with an olefin oxide, under pressure and in the presence of a basic catalyst (dimethylaniline or caustic soda, for example) yields water-soluble resinous hydroxyalkyl compounds which have been recommended for use as plastics, thickeners, and dressing and sizing agents.[141] Triethanolamine or other tertiary hydroxyalkylamines may also be condensed with olefin oxides to furnish more complex hydroxyalkyl ethers.[142]

A second important method for the production of monoalkyl ethers consists in treating either a glycol[143] or a chlorohydrin[144] with a dialkyl sulphate in the presence of caustic soda. The reactions in the case of ethylene glycol and chlorohydrin, condensed with diethyl sulphate to yield the monoethyl ether, are as follows:

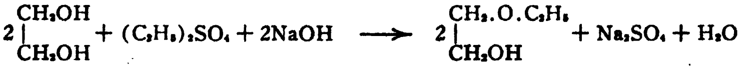
[142] I. G. Farbenindustrie A.-G., British Patents 364,000 and 364,104, 1930; *Brit. Chem. Abs.* **B**, 1932, 495.

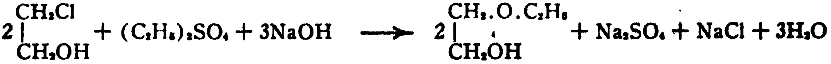
[143] Davidson, U. S. Patent 1,614,883, Jan. 18, 1927; assigned to Carbide and Carbon Chemicals Corp.; *Brit. Chem. Abs.* **B**, 1927, 237.

[144] Davidson, U. S. Patent 1,732,356, Oct. 22, 1929; assigned to Carbide and Carbon Chemicals Corp.; *Chem. Abs.*, 1930, **24**, 127.



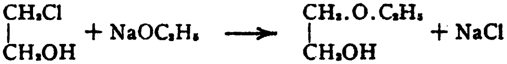
$$2\,\begin{array}{l}CH_2OH\\|\\CH_2OH\end{array} + (C_2H_5)_2SO_4 + 2NaOH \longrightarrow 2\,\begin{array}{l}CH_2.O.C_2H_5\\|\\CH_2OH\end{array} + Na_2SO_4 + H_2O$$

and



$$2\,\begin{array}{l}CH_2Cl\\|\\CH_2OH\end{array} + (C_2H_5)_2SO_4 + 3NaOH \longrightarrow 2\,\begin{array}{l}CH_2.O.C_2H_5\\|\\CH_2OH\end{array} + Na_2SO_4 + NaCl + 3H_2O$$

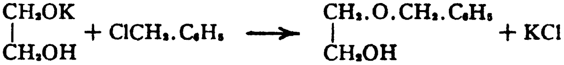
Another method of making monoalkyl ethers of the glycols consists in condensing an olefin oxide or a chlorohydrin with a sodium alcoholate. The reaction, with ethylene chlorohydrin, may be represented thus:



$$\begin{array}{l}CH_2Cl\\|\\CH_2OH\end{array} + NaOC_2H_5 \longrightarrow \begin{array}{l}CH_2.O.C_2H_5\\|\\CH_2OH\end{array} + NaCl$$

By this method, Cretcher and Pittenger[145] prepared the monoisopropyl, mono-n-propyl, monoisobutyl and monoamyl ethers of ethylene glycol. Similarly, ethylene glycol monobenzyl ether may be prepared from ethylene chlorohydrin and sodium benzylate.[146]

It is also possible to effect the synthesis by condensing a monopotassium derivative of a glycol with an alkyl chloride, e.g., the monopotassium salt of glycol condenses with benzyl chloride to form the monobenzyl ether (b.p., 132°-135° C. at 15 mm.):[146]



$$\begin{array}{l}CH_2OK\\|\\CH_2OH\end{array} + ClCH_2.C_6H_5 \longrightarrow \begin{array}{l}CH_2.O.CH_2.C_6H_5\\|\\CH_2OH\end{array} + KCl$$

Properties of Monoalkyl Ethers of Ethylene Glycol

The monoalkyl ethers of ethylene glycol are colorless, mobile liquids with practically no odor. They are solvents for cellulose nitrate, and the methyl ethers of the lower 1,2-glycols are also solvents for cellulose acetate. In general, they dissolve resins, oils and gums, the solubility of these materials increasing somewhat with increase in boiling point of the ether. Although the lower ethers are soluble in water, the butyl and isobutyl ethers of ethylene glycol have both upper and lower consolute temperatures.[147] The butyl ether of ethylene glycol is completely miscible with water above about 128° and below about 49° and similarly, the isobutyl ether, above about 150° and below about 25° C. The ethers are completely miscible with most organic solvents. The monoethyl ether is a powerful solvent for nitrocellulose, and resists dilution with non-solvents better than butyl acetate.[148] Table 105 summarizes some of the physical properties of the lower monoalkyl ethers of ethylene glycol.

The monoalkyl ethers of ethylene glycol have been proposed as solvents for cellulose acetate and nitrate in the lacquer industry[149] and also for use in anti-freeze solutions for automobile cooling systems.[150]

Ethylene glycol monomethyl ether is a solvent for cellulose esters and is specially adapted to the preparation of lacquers.[151] The carbonates of this and other ethers have been prepared by Drake and Carter.[152] The acetic acid ester of this monomethyl ether is a solvent for both cellulose acetate and nitrate and is miscible with water in all proportions.

Ethylene glycol monoethyl ether is a solvent for cellulose nitrate and is widely used in lacquer formulation.[153] This ether, which is marketed under the trade name of "Cellosolve", is not a good solvent for the resins commonly incorporated in cellulose lacquers, however. The addition of other solvents is thus often necessary to ensure a clear solution of gums and cellulose ester. It has also been suggested as a solvent in the preparation of urea-formaldehyde resins,[154] for dispersing direct dyes,[155] for certain pharmaceutical preparations,[156] and as a constituent of liquids for use in hydraulic brake systems.[157] Davidson[158] recommended a thinner for pyroxylin lacquers which contains not more than 30 per cent of ethyl acetate and ethyl alcohol, nor more than 20 per cent of the monoethyl ether of ethylene glycol and its acetate, together with a hydrocarbon solvent. Admixture of this ether with lubricants, such as castor oil, is said to yield a lubricating liquid of superior viscosity-temperature characteristics.[159] The ether has also been proposed as a solvent in the preparation of ink for printing on photographic plates.[160] An aluminum derivative of this ether, aluminum ethylene glycoloxide monoethyl ether, is a catalyst for the conversion of aldehydes to esters by the Cannizzaro reaction.[161]

Ethylene glycol monoethyl ether acetate ("Cellosolve Acetate") is a colorless liquid boiling at 153° C., which is a solvent for cellulose nitrate, ester gum, mastic, kauri, and shellac. It does not dissolve cellulose acetate.

[161] Young, U. S. Patent 1,630,593, May 31, 1927; assigned to Carbide and Carbon Chemicals Corp.; *Brit. Chem. Abs.* **B**, 1927, 618.

Ethylene glycol monoethyl ether stearate, melting at 55° to 60° C., has been proposed as a plasticizer.[162] 2-Alkoxyethyl esters of stearic, oleic, or other fatty acids have been suggested as softeners for cellulose derivatives.[163]

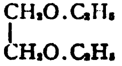
Ethylene glycol monopropyl ether has been suggested as a solvent in the preparation of lacquers, coating compositions and varnishes containing cellulose nitrate.[164] One of the advantages of the propyl ether is its lower miscibility with water than the corresponding methyl and ethyl ethers. Condensation products of naphthalene and the propyl ether have been proposed as wetting, cleansing, and emulsifying agents.[165]

Ethylene glycol mono-n-butyl ether is a high-boiling solvent of mild odor, known commercially as "Butylcellosolve". It is a solvent for cellulose nitrate and also for sandarac, mastic, kauri, cumarone resin, ester gum and elemi. It does not dissolve cellulose acetate or copal. It is especially recommended for brushing lacquers, for reducing the viscosity of lacquers and also for applying second coats over existing cellulose nitrate films.[166] It can be made by condensing ethylene oxide with n-butanol under pressure in the presence of sulphuric acid.[167] The solvent properties of various ethers have been discussed by Reid and Hofmann.[168]

Of the other mono-ethers of ethylene glycol, the monoamyl ethers have been proposed as solvents for cellulose nitrate in the manufacture of coating compositions.[169] The monophenyl ether [170] (boiling point, 237° C. at 760 mm., 165° C. at 80 mm.) and the monobenzyl ether [171] (boiling point, 132°-135° C. at 15 mm.) have also been prepared.[171a] The esters of various monoalkyl ethers of ethylene glycol with certain sulphonated carboxylic acids (e.g., sulphonated ricinoleic acid) have been suggested as wetting, foam-producing, and dispersing agents.[172] The tertiary phosphoric acid esters of monoalkyl or aryl ethers of ethylene, propylene, or butylene glycols can be prepared by the action of phosphorus oxychloride on the ether. They are said to be plasticizers in nitrocellulose lacquers and to be resistant to the action of light and low temperatures.[172a]

DIALKYL ETHERS OF ETHYLENE GLYCOL

Several dialkyl ethers of the lower glycols have been prepared. As solvents, however, they are not as satisfactory as the monoalkyl ethers. Ethylene glycol diethyl ether,



$$\begin{array}{l} CH_2O.C_2H_5 \\ | \\ CH_2O.C_2H_5 \end{array}$$

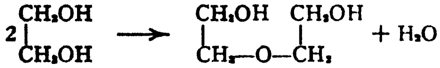
[172a] I. G. Farbenindustrie A.-G., German Patent 523,802, 1929; *Chem. Abs.*, 1931, **25**, 3667; British Patent 352,988, 1930; *Chem. Abs.*, 1932, **26**, 3391.

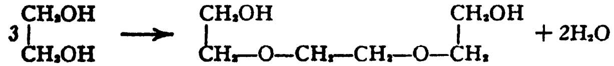
is a faintly odorous liquid (boiling point, 121° C.; D 0.853; and n^{20}_D 1.3914). It is considerably less soluble in water than the monoethyl ether and is a solvent for cellulose nitrate and for various gums, but not for cellulose acetate.[172b]

POLYGLYCOLS DERIVED FROM ETHYLENE GLYCOL

Polyglycols are substances derived from the simple 1,2-glycols by elimination of the elements of water from two or more molecules. They are produced by the action of dehydrating agents on glycols, during the hydration of olefin oxides to glycols (depending upon the proportions of olefin oxide and water employed), and by the interaction of olefin oxides with glycols. Diethylene glycol, triethylene glycol and polyethylene glycols as high as decaethylene glycol may be produced by elimination of water from ethylene glycol according to the reactions:

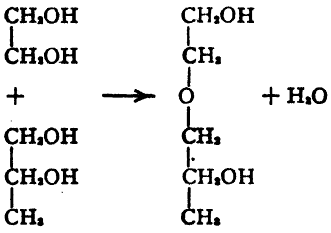


$$2\begin{array}{l}CH_2OH\\ |\\ CH_2OH\end{array} \longrightarrow \begin{array}{l}CH_2OH\quad CH_2OH\\ |\qquad\qquad\ |\\ CH_2{-}O{-}CH_2\end{array} + H_2O$$



$$3\begin{array}{l}CH_2OH\\ |\\ CH_2OH\end{array} \longrightarrow \begin{array}{l}CH_2OH\qquad\qquad\qquad\quad CH_2OH\\ |\qquad\qquad\qquad\qquad\qquad |\\ CH_2{-}O{-}CH_2{-}CH_2{-}O{-}CH_2\end{array} + 2H_2O$$

It is also possible to obtain mixed glycols. Thus, with ethylene and propylene glycols, ethylene propylene diglycol results according to the following condensation:



$$\begin{array}{c}CH_2OH\\ |\\ CH_2OH\\ +\\ CH_2OH\\ |\\ CH_2OH\\ |\\ CH_3\end{array} \longrightarrow \begin{array}{c}CH_2OH\\ |\\ CH_2\\ |\\ O\\ |\\ CH_2\\ |\\ CH_2OH\\ |\\ CH_3\end{array} + H_2O$$

Since the polyglycols are both ethers and alcohols, they are solvents for cellulose esters, gums, and resins. The best solvent is apparently obtained when the number of ether groups is equal to the number of hydroxyl groups, as in triethylene glycol. The polyglycols are very hygroscopic, ranking with glycerol in this respect. This property does not seem to affect their solvent powers greatly and is advantageous in some applications, particularly in the production of plastics such as motion picture film and celluloid where their incorporation gives increased pliability and flexibility even in dry atmospheres. A whole series of mono- and di-alkyl ethers, and mono- and di-esters, exists for each polyglycol.

DIETHYLENE GLYCOL

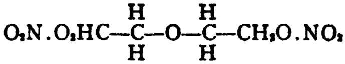
Diethylene glycol, $CH_2OH.CH_2.O.CH_2.CH_2OH$, is a colorless almost odorless liquid boiling at 244.5° C. at 760 mm. (D^{15}_{15} 1.1212; n^{20}_D 1.4475) and freezing at —10.5° C. Its heat of combustion is 566 kg.-cal. per mole. The viscosity of this compound is 0.50 and 0.27 poises at 15° C. and 27° C. respectively. At ordinary temperatures, it is freely miscible with water, lower alcohols, ethylene glycol, glacial acetic acid, acetone, furfural, pyridine, glycol diacetate, chloroform, nitrobenzene, and aniline but is immiscible with ether, benzene, toluene, carbon disulphide, and carbon tetrachloride. It is a solvent for cellulose nitrate and various dyes, but not for ester gum, shellac, cumarone resin, copals, or cellulose acetate. It absorbs more than its own weight of water in 9 days when kept in a closed space over water but undergoes no hydrolysis. Its density, viscosity, and refractive index at various temperatures have been determined by Rinkenbach.[173]

[172b] Davidson, *Ind. Eng. Chem.*, 1926, 18, 669.

Diethylene glycol can be obtained by the partial dehydration of ethylene glycol and by the action of ethylene oxide on glycol, but, according to Schrader,[174] the diethylene glycol which is marketed is a by-product of the hydration of ethylene oxide to glycol. Depending upon the relative amounts of oxide and water, triethylene, tetraethylene, and higher glycols may also be produced in smaller amounts.

Diethylene glycol has proved to be an ideal lubricant for wool spinning.[175] Impregnation of the fiber with this material renders unnecessary the use of oils and so obviates the costly process of scouring for oil elimination after spinning. Diethylene glycol has been suggested for use also in liquid heat-transfer media,[176] adhesives[177] and abrasive materials.[178]

Of the derivatives of this diglycol, the dinitrate,



$$O_2N.O_2HC-\overset{H}{\underset{H}{C}}-O-\overset{H}{\underset{H}{C}}-CH_2O.NO_2$$

is one of the more important. This was first prepared by Rinkenbach,[179] by nitration at below 10° C. in the presence of a nitrating mixture containing 25 per cent nitric acid, 5 to 10 per cent water, and the remainder, sulphuric acid. Yields of 60 to 70 per cent were obtained. The nitrating conditions were later improved to give a yield of about 85 per cent of the theoretical.[180] The pure dinitrate is a clear colorless liquid of greater fluidity than nitroglycerol. It is completely miscible with most organic solvents except ethyl alcohol, carbon tetrachloride and carbon disulphide. Its solubility in water is 4.1 grams per liter at 24° C. and it is only slightly hygroscopic. It freezes at —11.3° C. and has a specific gravity at 15° C. of 1.3908, refractive index of 1.4536, heat of combustion, 2798 gm.-cal. per gram at constant volume of 2792 gm.-cal. per gram at constant pressure, and a vapor pressure of 0.007 mm. at 22.4° C. It can be ignited only by heating and is less sensitive to shock than nitroglycerol or glycol dinitrate. When mixed with these compounds, it can be completely detonated and shows an explosive effect only a little less than either of them. It is, however, definitely toxic, the symptoms being similar to those produced by nitroglycerol.

Diethylene glycol monoacetate is a solvent for cellulose acetate and nitrate, rosin and gum camphor. It is miscible with water and aromatic hydrocarbons. The polyalkylene glycol esters may be made either by esterifying the polyglycol or by heating an olefin oxide with an organic acid in the presence of sulphuric acid (in the latter process, acetates of monoglycols are also formed).[181] Mixtures of the mono- and di-oleic and stearic acid esters of diethylene glycol (the oleate having p_H 5.0 and the stearate p_H 6.3) have been prepared. The former is a liquid insoluble in water but soluble in ethyl alcohol, esters and hydrocarbons. It can be used in weaving silk and rayon, and, in naphtha solution, for dry cleaning. Diglycol stearate is a solid, melting at 58°-60° C. Its dispersions in warm water serve to suspend abrasives, graphite, and pigments. Diglycol stearate is recommended also for the oiling and washing of wool and in the weaving of silk and rayon.[182]

[179] *Ind. Eng. Chem.*, 1927, 19, 925.

[180] Rinkenbach and Aaronson, *Ind. Eng. Chem.*, 1931, 23, 160; the nitration has been described also by Hough, Canadian Patent 325,098, 1932; *Chem. Abs.*, 1932, 26, 5578.

Mixed di-esters of diethylene glycol containing aliphatic acid radicals of less than 6 carbon atoms and (esterified with the second hydroxyl group) of more than 10 carbon atoms, are said to be fixatives for perfumes.[183] A product of this type, for example, is diethylene glycol monoacetate esterified with coconut oil acids, or oleic acid.

Diethylene glycol monoethyl ether is a liquid boiling at 198° C. at 760 mm. (D^{15}_{15} 0.9996, and n^{20}_D 1.4240). It has been marketed commercially under the trade name of "Carbitol". It may be manufactured by the condensation of ethylene oxide with ethylene glycol monoethyl ether at 70° to 250° C. under pressure.[184] It is a solvent for cellulose nitrate, and various gums and dyes and has found application in the manufacture of textile soaps, in dye-printing, and as a plasticizer. The monoalkyl ethers of the polyglycols have been proposed as constituents of anti-freeze solutions.[185]

Mono- and di-ethers of diethylene glycol have been proposed as wetting agents [186] and lubricants [187] in the treatment of cellulose textiles. The acetal of diethylene glycol monoethyl ether is suggested as a component of a cellulose acetate composition.[188] Leaper [188a] suggested using a solution of potassium hydroxide in "Carbitol" for the determination of saponification number of fats and waxes.

Diethylene glycol monobutyl ether (trade name, "Butylcarbitol") is a liquid of mild odor, boiling at 222° C., which dissolves cellulose nitrate and various gums but not cellulose acetate. It is miscible with water and hydrocarbons.

HIGHER POLYGLYCOLS

Triethylene glycol boils at 276° C. at 760 mm. Its monoethyl ether boils at 248° C. and has a specific gravity of 1.0566 at 15° C. The boiling points of tetraethylene glycol and its monoethyl ether are 230° C. at 25 mm., and 284° C. at 760 mm., respectively.[189] Both the polyglycols and their ethers are practically odorless.

The polyalkylene glycol ethers can be produced by the treatment of aliphatic alcohols with an excess of an olefin oxide in the presence of either acid or basic catalysts, such as strong acids, tertiary amines, and alkali alcoholates. A product, consisting mainly of ethyl ethers of tetraethylene glycol, is obtained by treating 230 parts of ethanol with 880 parts of ethylene oxide at 80° to 100° C. in the presence of 3 parts of sodium as catalyst.[190] Such products are said to be valuable assistants in the textile industry.[191]

Tetraethylene glycol (boiling point, 190° C. at 3 mm.) may be synthesized by the condensation of triethylene glycol with ethylene oxide under pressure.[192]

HIGHER 1,2-GLYCOLS

Propylene glycol (propane-1,2-diol, $CH_3.CHOH.CH_2OH$) is obtained from either of the propylene chlorohydrins by treatment with sodium bicarbonate solution under pressure. The production of this and other 1,2-glycols can be conducted by the general methods previously discussed in the section on ethylene glycol. The other method of preparing glycols, the hydrolysis of olefin dichlorides (or dihalides, generally), does not appear to be as applicable to the preparation of propylene glycol as to that of ethylene glycol, however. Wurtz[193] prepared propylene glycol by the action of silver acetate on propylene dibromide followed by hydrolysis of the diacetate formed, but hydrolysis of propylene dihalides either with lead oxide and water[194] or with aqueous potassium carbonate[195] leads to the formation of acetone and propionaldehyde as well as glycol. It is interesting to note that this glycol can be prepared by the hydration of allyl alcohol in the presence of 10 per cent aqueous hydrochloric acid,[196] thus:

$$CH_2OH.CH{=}CH_2 + H_2O \longrightarrow CH_2OH.CHOH.CH_3$$

Propylene glycol does not appear to offer any advantages over ethylene glycol in the various important applications of this latter substance. It has been proposed as a lubricant, either alone or mixed with other glycols, glycerol, or graphite, in refrigerating machines operating with ethane, propane, butane, or methyl and ethyl chlorides.[197]

Propylene glycol is a colorless sweet-tasting liquid boiling at 188° to 189° C. at 760 mm. and 96° to 98° C. at 21 mm. It is miscible with water and alcohol and dissolves in 12 to 13 volumes of diethyl ether. In chemical properties it closely resembles ethylene glycol. Thus, it readily forms both mono- and diesters and also mono- and di-alkyl ethers. Propylene glycol dinitrate is a colorless liquid closely resembling ethylene glycol dinitrate.[198] Heating with dilute acids to high temperatures converts the glycol into propionaldehyde and other substances. By heating propylene glycol to 170° C. with dilute sulphuric acid, Rix[199] obtained propionaldehyde, acetone, and methylacraldehyde. Linnemann[200] also obtained propionaldehyde by heating the glycol with very dilute hydrochloric acid to 220° C. As in the conversion of ethylene glycol into acetaldehyde under similar conditions, the reaction possibly takes place through the intermediate formation of an olefin oxide (or a dioxan derivative) which can isomerize to an aldehyde. Propylene glycol is converted into water and propionaldehyde by passing over pumice at 500° C., or over alumina at 250° to 260° C.[201]

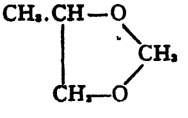
Oxidation of propylene glycol with nitric or chromic acid results in the formation of glycollic, oxalic and acetic acids. Catalytic oxidation in the presence of a glowing platinum spiral was found to yield methylglyoxal and formaldehyde.[202]

Propylene glycol readily yields cyclic acetals by condensation with aldehydes. With formaldehyde, for example, in the presence of a little ferric chloride as catalyst, this glycol yields the ether,



boiling at 90° C.[203]

Propylene glycol, on treatment with sulphur monochloride or with gaseous hydrogen chloride, yields propylene chlorohydrin.[204] On dehydration it yields propylene oxide and a series of polyglycols in a manner similar to that of ethylene glycol. Various metallic derivatives (e.g., sodium compounds) of propylene glycol are also known.

Propylene glycol has a more acrid taste than glycerol or ethylene glycol. It exerts a local burning sensation on the tongue without, however, injuring the oral mucosa. It seems generally agreed that propylene glycol is much less toxic than ethylene glycol.[205] Intravenous fatal doses per kilogram of body weight were 16.8 milligrams for rats and 5.25 milligrams for rabbits.[206]

A considerable number of mono- and di-alkyl ethers of propylene glycol have been prepared. The monoalkyl ethers may be obtained by heating aliphatic alcohols under pressure with propylene oxide, whereas the corresponding di-ethers may be prepared from propylene glycol or chlorohydrin by condensation with a dialkyl sulphate in the presence of alkali.[207] The pure ethers, and their mixtures, may be used as solvents for gums, resins, and cellulose esters.[208] Table 106 gives the physical constants of some of the mono-ethers of propylene glycol.[209]

The monoaryl ethers, such as the monophenyl and monobenzyl ethers, are also solvents for cellulose esters. Tertiary esters of phosphoric acid with monoalkyl ethers of ethylene, propylene or butylene glycol have been suggested as softening and gelatinizing agents for cellulose acetate by Schönburg and Wick.[209a] The mono-ethers surpass the di-ethers in solvent power and may be used in conjunction with a wide variety of other solvents or diluents in the preparation of lacquers or the like.

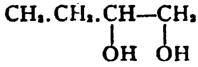
Butylene Glycols. Three butylene-1,2-glycols are known:

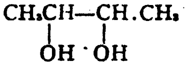
Butane-1,2-diol,



$$CH_3.CH_2.\underset{OH}{CH}—\underset{OH}{CH_2}$$

is the glycol corresponding with 1-butene and was obtained by Grabovsky and Saytzeff[210] from 1-butene dibromide. It boils at 191°-192° C. at 747 mm.

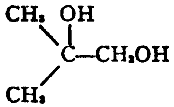
Butane-2,3-diol,



$$CH_3CH—CH.CH_3 \quad \text{with } OH \cdot OH$$

the glycol derived from 2-butene, boils at 183°-184° C. It can be obtained by the hydration of β-butylene oxide (3 volumes of water to 1 volume of oxide) at 100° C.[211]

2-Methylpropane-1,2-diol (also called isobutylene glycol),



is the glycol derived from isobutylene, from which hydrocarbon it can be prepared (though in poor yield) by oxidation with neutral aqueous permanganate.[212] It was made by Nevole[213] by heating isobutylene dibromide with aqueous potassium carbonate. Its boiling point is 176°-178° C. at 760 mm.

The higher glycols are of comparatively little interest and will not be considered in detail. In general chemical properties they resemble ethylene and propylene glycols. On dehydration they yield olefin oxides and heating with dilute acids at high temperatures tends to dehydrate them with the production of ketones, the dehydration often being accompanied by a molecular rearrangement. On being passed over a catalyst, for example, copper with an alkaline earth promoter at 210° to 220° C., isobutylene glycol forms methyl ethyl ketone and trimethylethylene glycol yields methyl isopropyl ketone.[214] 4-Hydroxy-2-butanone (acetylethyl alcohol) can be obtained by treating 1,3-butylene glycol with a dehydrogenating agent under reduced pressure at high temperature, according to Hilger.[215]

With some of the higher 1,2-glycols this conversion into ketones is also accompanied by an intramolecular change. For example, pinacone (tetramethylethylene glycol) is converted into the ketone, pinacolin, even under the influence of a weak acid (oxalic acid). The reaction can be represented as follows:

---

[210] *Ann.*, 1875, **179**, 325; *Chem. Soc. Abs.*, 1876, **29**, 542.

[211] Eltekow, *J. Russ. Phys.-Chem. Soc.*, 1882, **14**, 355; *Chem. Soc. Abs.*, 1883, **44**, 566.

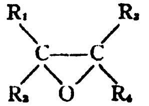
Chapter 23

Production, Properties, and Uses of Olefin Oxides and Their Derivatives

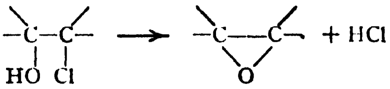
The olefin oxides are neutral substances of the general structure



where R_1, R_2, R_3, and R_4 may be hydrogen atoms or alkyl and aryl groups. These substances, particularly the ethylene and propylene homologues which are already finding applications in the industry, are capable of an astounding number of condensation reactions with other organic compounds and on this account will undoubtedly be used extensively in industrial organic synthesis.

PRODUCTION OF OLEFIN OXIDES

Olefin oxides may be produced by a number of reactions but the only important industrial method involves the elimination of hydrogen chloride from α-chlorohydrins by the use of alkalies. This reaction can be represented by



Wurtz[1] was the first to show that olefin oxides were obtained by the action of potassium hydroxide on chlorohydrins and obtained ethylene oxide in this way from ethylene chlorohydrin. This reaction is considered in greater detail later. Distillation of chlorohydrins over lead or zinc oxide yields only the corresponding aldehyde.[2]

Ethylene oxide may be prepared from ethylene chlorohydrin and mono-sodium glycol at 130° C.;[3] from ethylene iodide or ethylene bromide and silver oxide at 150° C. and 250° C., respectively;[4] and from ethylene bromide or ethylene chlorobromide and sodium oxide at 180° C.

Although theoretically olefin oxides should result from the dehydration of α-glycols, in actual practice this process usually produces a mixture of other substances such as aldehydes, ketones and dioxan derivatives. Thus, ethylene glycol on being heated either alone or with dehydrating agents such as zinc chloride or dilute acids yields acetaldehyde, dioxan and other substances according to the conditions. An example of the direct dehydration of an α-glycol to an olefin oxide has been reported by Gardeur,[5] who showed that triphenylethylene glycol in benzene solution could be dehydrated with phosphorus pentoxide to yield triphenylethylene oxide:

---

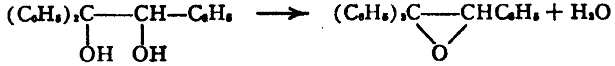
[2] Kaschirsky, *Ber.*, 1877, 10, 1104.

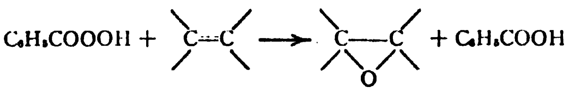
[3] Scheitz, *Z. für Chem.*, 1868, 379.

[4] Greene, *Compt. rend.*, 1878, 86, 624, 1141; *Chem. Soc. Abs.*, 1878, 34, 656; *Jahresber.*, 1877, 522.



$$(C_6H_5)_2C(OH)—CH(OH)—C_6H_5 \longrightarrow (C_6H_5)_2C\overset{O}{—}CHC_6H_5 + H_2O$$

In some cases the olefin oxides may be prepared by the direct oxidation of ethylene hydrocarbons. Thus, by passing isobutylene into an aqueous solution of iodine and potassium iodide at ordinary temperature, Pogorzelski[6] obtained a mixture of isobutylene oxide and trimethylcarbinol. Perbenzoic acid reacts with olefins in indifferent solvents to yield olefin oxides:[7]



By this interesting reaction, Prileschajew was able to prepare tetramethylethylene oxide, octylene oxide, diisobutylene oxide, decylene oxide, and pinene oxide from the corresponding unsaturated hydrocarbons.

Lenher[8] showed that ethylene and propylene oxides (as well as other substances) are formed in the reaction between an excess of ethylene or propylene, respectively, and oxygen, at 500° to 600° C. The best yield of ethylene oxide, namely 21 per cent of the total ethylene consumed, was obtained by passing a mixture of 80 volumes of ethylene and 10 volumes of oxygen through a pyrex tube at a temperature of about 535° C. with a contact time of 3 seconds.

Olefin oxides may be obtained indirectly by a number of other methods, such as the condensation of aldehydes with monochloroacetic esters and the action of nitrous acid on certain aminoalcohols, but these processes are of academic interest only.

As previously stated, the only industrially valuable method of manufacture of the lower olefin oxides is by elimination of hydrogen chloride from α-chlorohydrins in the presence of alkalies, the reaction discovered by Wurtz.[9] The procedure was commercialized by the Badische Co.[10] In their process, glycol formation was minimized by adding a warm solution of alkali to a warm solution of ethylene chlorohydrin.

The preparation of olefin oxides having from 5 to 8 carbon atoms per molecule was described by Walker.[11] The raw material is a cracked petroleum fraction, boiling from 35° to 125° C. From this fraction a mixture of chlorohydrin and hydrocarbons is obtained by treatment with hypochlorous acid. The hydrocarbons are separated by distillation and the chlorohydrins converted to the corresponding oxides by heating with slaked lime. Distillation of the alkali mixture yields an oily product, which after washing with 50 per cent caustic soda solution, dehydrating with potassium carbonate or calcium chloride, and redistilling gives a water-white mixture of olefin oxides. These oxides are insoluble in water, possess an ethereal odor, and are miscible with the usual organic solvents (alcohol, carbon tetrachloride and benzine). They are solvents for pyroxylin, varnish gums, asphalts and oils.

[10] German Patent 299,682, 1915; *J.S.C.I.*, 1920, 39, 582A.

[11] U. S. Patent 972,952, Oct. 18, 1910; assigned to Maas and Waldstein; *Chem. Abs.*, 1911, 5, 150. See also British Patent 22,309, 1910; *Chem. Abs.*, 1911, 5, 3158; German Patent 254,858, 1910; *Chem. Abs.*, 1913, 7, 1587.

According to Brooks,[12] the yields of olefin oxides depend upon the concentration of the alkali and upon the rapid removal of the volatile oxides from the reaction mixture. Thus, when a 20 per cent solution of ethylene chlorohydrin is added to a 20 per cent solution of sodium hydroxide, only about 12 per cent of ethylene oxide is obtained. On the other hand, by using equal parts by weight of ethylene chlorohydrin (80 per cent chlorohydrin and 20 per cent water) and solid sodium hydroxide, the yield of oxide is 83 per cent. Quicklime also gives excellent yields, 70 to 90 per cent of the theory, when the chlorohydrin is substantially anhydrous. If much water is present the yield of oxide is very poor because of the formation of glycols and condensation products of unknown structure.

In the process mentioned above, the substantially anhydrous chlorohydrin is allowed to flow slowly onto solid caustic soda or quicklime, placed in an apparatus provided with means of stirring the contents and with outlets. The heats of formation of ethylene, propylene and butylene oxides are sufficient to distil the oxides almost as fast as they are formed. Means should be provided for heating the apparatus for making the higher olefin oxides. It is important to remove the oxides as fast as they are formed, which requires reduced pressure when working with the higher oxides. Ethylene, propylene, and butylene chlorohydrins react vigorously with caustic soda or lime at ordinary temperatures but most of the chlorohydrins containing 8 to 12 carbon atoms per molecule require several hours' heating at 100° to 150° C. to eliminate all the combined chlorine.

Burdick[13] expressed the opinion that the use of concentrated solutions of chlorohydrins is not essential. He obtained good yields (90 per cent or more) from solutions containing 10 per cent of chlorohydrins when the olefin oxide formed was removed at such a rate that no substantial accumulation of it occurred in the reaction mixture. This may be accomplished by heating the solution under atmospheric or reduced pressure, or in other ways. Thus, a 10 per cent ethylene chlorohydrin solution is heated to boiling in a kettle fitted with a rectifying column and a reflux condenser, and a strong solution of sodium hydroxide is added continuously. The oxide, together with steam, passes into the rectifying column where most of the steam is condensed while the ethylene oxide passes into a separate condenser cooled with brine. According to Burdick,[14] propylene oxide can be produced from dilute (10 per cent) solutions of propylene chlorohydrin in a similar manner, the yield in this case also being 90 per cent of the theoretical.

A continuous process for making olefin oxides from chlorohydrins was described by Walker, Schrader and Wiedbruck.[15] It involves the interaction of hot aqueous solutions of chlorohydrins with an alkali (milk of lime) under reduced pressures so that the liquid products boil at 80° C.

The solutions of alkali and chlorohydrins are simultaneously introduced into a reaction vessel divided into several compartments by baffles to promote good mixing. The mixture is heated by steam admitted at the bottom of the vessel. Steam and oxides distil and pass through a water condenser, in which the steam is condensed and flows back to the reaction vessel. The vapors of oxides are conducted through two coolers connected in series, the first of which is maintained at the higher temperature, to permit a partial separation of the oxides. Any uncondensed vapors escaping from the coolers are led through a scrubbing tower where they are reabsorbed by the incoming solution of chlorohydrins. Permanent gases leave the system through an outlet at the top of the scrubbing tower. The hot exhausted liquid from the reaction vessel is withdrawn through a heat exchanger, which serves to pre-heat the incoming chlorohydrin solution.

[14] U. S. Patent 1,589,359, June 22, 1926; assigned to Carbide and Carbon Chemicals Corp.; *Brit. Chem. Abs.* B, 1926, 692.

[15] U. S. Patent 1,792,668, Feb. 17, 1931; assigned to T. Goldschmidt A.-G. See also British Patent 293,763, 1928; *Chem. Abs.*, 1929, 23, 1648; French Patent 656,996, 1928; *Chem. Abs.*, 1929, 23, 4229; German Patent 541,769, 1927; *Chem. Abs.*, 1932, 26, 2466.

The hydrolysis of ethylene chlorohydrin by aqueous alkaline solutions was also recommended by Saunders and Wignall.[16] A mixture of chlorohydrin vapors and steam is treated countercurrently with a stream of alkali solution. Ethylene oxide is the main product when a concentrated solution of sodium hydroxide is used. Substitution of sodium carbonate for sodium hydroxide results in the formation of glycol.

Relatively low temperatures and reduced pressures were recommended by Thole, Birch and Scott.[17] For example, aqueous solutions of ethylene chlorohydrin and sodium hydroxide are mixed at 10° to 20° C. and then introduced into a packed column at 30° to 50° C. and a pressure of 95 to 105 mm. of mercury. Ethylene oxide is liberated at once and collected in the form of its solid hydrate.

As previously mentioned, conversion of ethylene chlorohydrin to ethylene oxide may take place in the vapor phase. Oehme[18] suggested leading chlorohydrin vapors over solid alkalies. Aliphatic or hydroaromatic oxides are produced by passing the vapors of the corresponding 1,2-chlorohydrins, alone or mixed with steam, over catalysts such as magnesium oxide or copper phosphate, at 250° to 330° C.[19]

Ethylene oxide is said to result on conducting ethylene, air, steam and hydrogen over a catalyst heated to 150° to 400° C.[19a] Catalysts suggested are silver, bismuth or antimony, or a mixture containing two or more of the following metals: antimony, lead, bismuth, silver, nickel, tin or arsenic. The amount of carbon dioxide formed may be reduced by adding carbon dioxide to the reacting gases and the yield of ethylene oxide increased by lowering the pressure below atmospheric.

A method for the separation of individual olefin oxides from mixtures by fractional distillation under superatmospheric pressure was described by Finkelstein.[20]

PROPERTIES OF ETHYLENE OXIDE

Ethylene oxide is a colorless, highly volatile liquid which boils at 10.7° C., melts at —111.3° C. and has d_4^7 0.997. It is completely miscible with water and, like its homologues, is a good solvent for cellulose esters.[20a] On account of its extreme volatility, however, ethylene oxide is of little value as an industrial solvent. It is chiefly of importance for the multiplicity of its reactions which render it an admirable raw material for numerous organic syntheses.[21] In the following account it is possible to outline very briefly only the more important of these, which are, however, typical of the α-oxides as a class.

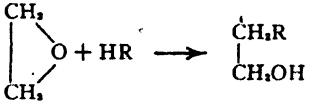
Ethylene oxide, and α-oxides generally, reacts with numerous organic substances containing an easily replaceable hydrogen atom, such as alcohols, phenols, or amines, and also with water. The reaction can be summarized by the following:



Reaction with Water

Ethylene oxide reacts slowly when heated with water in a sealed tube to yield ethylene glycol, a reaction first discovered by Wurtz.[22] The simultaneous formation of diethylene glycol and triethylene glycol as by-products was noted by Lourenço.[23] The reaction is greatly accelerated by catalysts such as sulphuric or hydrochloric acids,[24] particularly the former. According to Eltekov,[25] the ease of hydration of the lower olefin oxides depends mainly on the constitution of the oxide. For example, isopropylethylene oxide and sym-methylethylethylene oxide combine slowly with water, while isobutylene oxide reacts vigorously with it even at ordinary temperatures, with marked evolution of heat. In the industrial hydration of ethylene oxide to glycol [26] dilute sulphuric acid is used as a catalyst and it is necessary to take account of the considerable heat of reaction (about 25 kilogram-calories per mole). Youtz [27] stated that the formation of polyglycols during the hydration of olefin oxides can be avoided provided a large volume of water is present. He recommended 20 moles of water per mole of oxide.

Reaction with Alcohols and Phenols

The reaction between alcohols, or phenols, and olefin oxides is analogous to that with water and yields monoethers of the corresponding glycols. Thus, ethylene oxide when heated with ethyl alcohol yields ethylene glycol monoethyl ether: [28]

[28] See for example, Young, U. S. Patent 1,696,874, Dec. 25, 1928; assigned to Carbide and Carbon Chemicals Corp.; *Chem. Abs.*, 1929, 23, 846; Loehr, German Patent 580,075, 1933; assigned to I. G. Farbenindustrie A.-G.; *Chem. Abs.*, 1933, 27, 4814.

The similar reaction with phenol produces the monophenyl ether.[29] A small amount of sulphuric acid is effective in catalyzing this reaction,[30] probably by the intermediate formation of a sulphuric ester of ethylene glycol. Ethylene glycol monoethyl ether, propylene glycol monoethyl ether and ethylene glycol monophenyl ether are prepared[31] from the corresponding oxides by continuously passing the oxide mixed with the required alcohol or phenol under a pressure of 5 to 30 atmospheres through an enameled reaction tower heated to about 180° C. Catalysts for such reactions include dialkyl sulphates,[32] and certain acidulated hydrosilicates (especially those of aluminum) showing a p_H value less than 3 in aqueous suspensions.[33]

Various highly viscous ethers are obtained by condensing olefin oxides with polyhydric alcohols (e.g., glycerol, sorbitol, pentoses and ketoses) in the presence of sulphuric or boric acid catalysts.[34] Sorbitol heated with ethylene oxide in an autoclave at 140° C. for 12 hours yields sorbitol hexa-(β-hydroxyethyl) ether, and pentaerythritol similarly treated in the presence of boric acid, a syrupy ether. These ethers may be used as substitutes for polyhydroxy alcohols in paper making, dyeing, the explosives industry, textile processes, lubricants for machinery or as solvents or separating agents.[34a] Acylation with formic, acetic or benzoic acids or with polybasic acids, such as oxalic, succinic or phthalic, yields substances which may be employed as plasticizing materials. The esters formed with nitric acid may be used in the preparation of films, plastics, lacquers or explosives.

The extension of this reaction of olefin oxides with polyhydric alcohols to the production of hydroxyalkyl derivatives of the polymerized alcohols[35] (e.g., polyvinyl alcohol) and of the more complex carbohydrates (cellulose and starch) has attracted attention because the products are likely to prove useful in the textile industry. Catalysts for condensation of this kind, particularly those with cellulose and starch, include such basic materials as sodium hydroxide,[36] aqueous ammonia or hydroxyalkylamines,[37] and tertiary amines (dimethylaniline).[38] Mineral acids have been proposed also for catalyzing the combination of olefins with cellulose.[39] The hydroxyethers obtained by these methods can be converted into esters by heating with acid anhydrides in the presence of benzine.[40]

Shoruigin and Rimashevskaya[40a] studied the properties of cellulose hydroxyethyl ether and its acetate. Bleached cotton (linters), viscose silk and copper-ammonium silk were mercerized and then heated for 18 hours at 30° C. with ethylene oxide. The product was dissolved in water and precipitated from solution with acetone, giving a fine white flocky material which decomposed at about 245° to 250° C. This substance was soluble in water, acetic acid, and fused phenol, but insoluble in acetone, alcohol and ether. The iodine number varied from 2.40 to 3.88 and the compound appeared to correspond with the formula $C_6H_7O_2(OH)_2OCH_2CH_2OH$. An acetic acid-acetone mixture containing sulphuric acid, gave a triacetate which decomposed at 192° to 104° C. It was soluble in acetone, chloroform and acetic acid and its iodine number was 5.2-5.3.

The glycol monoalkyl esters, or their derivatives, have been suggested as sealing liquids for gasometers or as cooling liquids (to reduce the freezing point of water) for internal-combustion engines.[41]

By employing a considerable excess of olefin oxide over that required to form the monohydroxy ether of the reacting alcoholic compound, it is possible to make polyolefin glycol ethers as the main products. Loehr[42] suggested the use of sodium as a catalyst for such a reaction. Introduction of ethylene oxide into anhydrous ethyl alcohol, containing a small proportion of sodium, leads to the formation of the ethyl ether of tetraethylene glycol and its higher homologues. Monophenyl and monotolyl ethers of the polyolefin glycols can be prepared by passing an excess of the olefin oxide into the fused phenol to which sodium hydroxide has been added.[43]

The esterification or etherification products of non-carbohydrate organic compounds containing hydroxyl or carboxyl groups (such as alcohols from the catalytic reduction of oils and fats, or from oxidized paraffin wax, or castor oil, oleic or palmitic acids) with polyethylene glycols or their monoethers or monoesters (or an equivalent quantity of ethylene oxide or ethylene chlorohydrin) have been suggested as wetting, foaming, or dispersing agents.[43a]

The production of polyolefin glycol ethers by condensation of olefin oxides with glycols has been described by Davidson.[44] He suggested the use of these ethers,[45] as well as esters of the ethers of glycols and polyglycols,[46] in paint, varnish and lacquer removers.

REACTION WITH HYDROGEN HALIDES

Ethylene oxide reacts not only with anhydrous hydrogen chloride but also with aqueous solutions of certain metallic chlorides to form chlorohydrin. The reaction of the olefin oxides with hydrogen chloride is a general one, although it often yields a mixture of isomeric chlorohydrins. Hydrogen bromide reacts in a similar manner to yield bromohydrins, and in some cases hydrogen iodide combines with the oxides to give iodohydrins.[47]

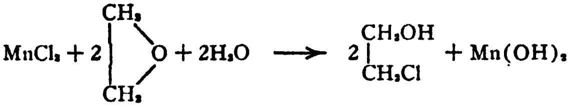
The reaction of ethylene oxide, and olefin oxides generally, with aqueous solutions of hydrolyzable metallic halides is made the basis of a test for such oxides.[48] With chlorides of aluminum, magnesium, iron, tin, zinc and manganese in neutral solutions, ethylene oxide absorbs the acid freed by dissociation and hydrolysis, and the metallic hydroxide is precipitated. This reaction can be illustrated as follows:



The appearance of a precipitate in a controlled test solution is evidence of the presence of an olefin oxide. Although magnesium chloride solution has been most frequently used,[49] Lenher[50] concluded that a saturated aqueous solution of manganous chloride gives the more sensitive and easily controlled test.

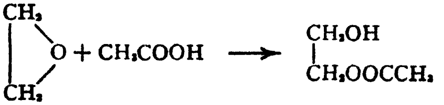
In ether solutions ethylene oxide reacts with magnesium bromide to give a product having the formula $CH_2BrCH_2OMgBr.(C_2H_5)_2O$. Hydrolysis of this substance yields bromohydrin and magnesium bromide and hydroxide.[51] This latter reaction may be represented by:

$$2CH_2BrCH_2OMgBr.(C_2H_5)_2O + 2H_2O \longrightarrow CH_2BrCH_2OH + MgBr_2 + Mg(OH)_2 + 2(C_2H_5)_2O$$

Ethylene oxide can combine with ethylene chlorohydrin in the presence of a small amount of sulphuric acid to yield dioxan as well as β-chloroethyl β-hydroxyethyl ether and ββ′-chloroethoxyethyl β-hydroxyethyl ether.[52]

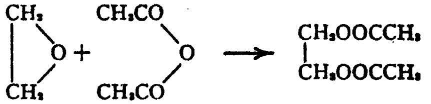
Reaction with Organic Acids and Acid Anhydrides

The reaction of olefin oxides with organic acids appears to be a fairly general method for the preparation of the mono-esters of the corresponding glycol, but if an organic acid anhydride is employed the di-ester of the glycol is formed. By heating ethylene oxide with glacial acetic acid, Wurtz[53] obtained ethylene glycol monoacetate and the diacetate from acetic anhydride.[54] These reactions may be represented as follows:



---

[47] Wurtz, *Ann. chim.*, 1863, (3) 69, 317, 355.
[48] Walker, *Ber.*, 1901, 34, 4115; Wurtz, *Ann.*, 1860, 116, 252.
[49] Mulliken. "Identification of Pure Organic Compounds." John Wiley and Sons, New York, 1905, 1, 160.
[50] *J.A.C.S.*, 1931, 53, 3739.
[51] Ribas and Tapia. *Anal. Fis. Quim.*, 1932, 30, 778; *Brit. Chem. Abs.* A, 1933, 48.
[52] Fourneau and Ribas, *Bull. soc. chim.*, 1927, (4) 41, 1046; *Brit. Chem. Abs.* A, 1927, 1052.
[53] *Ann.*, 1860, 116, 249.
[54] *Ann.*, 1860, 113, 255.



These important reactions, which constitute industrial methods for making the esters of the lower glycols, are catalyzed by small amounts of sulphuric acid[55] and also by ferric chloride.[56] A continuous process for the manufacture of ethylene glycol monoacetate consists in passing a mixture of ethylene oxide and glacial acetic acid, under pressures of 5 to 30 atmospheres, through a reaction tower heated to 130° C.[57]

Wax-like bodies are obtained on heating alkylene oxides with a mixture of oxidized montan wax and naphthenic acids.[58]

Catalysts for accelerating the combination of olefin oxides with carboxylic acids consist of acidulated hydrosilicates (particularly those of aluminum) which, on dispersion in water, exhibit a p_H value of not more than about 3.[59] Thus, on slowly introducing 80 parts of ethylene oxide into a mixture of 20 parts of the hydrosilicate "Tonsil AC" with 400 parts of glacial acetic acid at 25° C., a vigorous exothermic reaction takes place. The mixture is maintained at 50° to 55° C. (by cooling) and is stirred for 15 minutes after all the oxide has been added. On filtering and distilling, the products are 180 parts of a mixture of ethylene glycol mono- and di-acetates together with a small amount of high-boiling substances, presumably polyethylene glycol acetates.

Sodium benzoate has been suggested as a catalyst for the reaction between ethylene oxide and fused benzoic acid.[60]

Dibasic acids (phthalic, succinic or tartaric) are converted into their corresponding ethyl esters by heating with ethylene oxide at 60° to 70° C.[61] Rosin reacts with oxide at 160° to 170° C. under pressure to yield resins which may be employed in the manufacture of lacquers and varnishes.[62]

REACTION WITH AMMONIA AND AMINES

Ethylene oxide reacts energetically with dilute or concentrated ammonia solution to yield a mixture of three basic substances, mono-, di-, and tri-ethanolamines,[63] having the formulas $NH_2CH_2CH_2OH$, $NH(CH_2CH_2OH)_2$, and $N(CH_2CH_2OH)_3$, respectively. It was shown by Knorr[64] that the presence of a small proportion of water is essential to this reaction, since pure ethylene oxide does not react with dry ammonia. These reactions are of industrial importance since the ethanolamines are used on a substantial scale as emulsifying agents and in other ways. A discussion of the properties of the simple ethanolamines is given later.

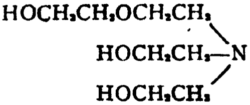
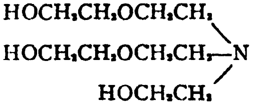
The reaction between α-oxides (particularly ethylene oxide) and ammonia in aqueous solution can be made to yield complex compounds by using a large excess of the oxide. Such substances are probably formed by further action of the excess olefin oxide on the simple ethanolamine initially formed. Thus, a mixture of mono-, di-, and tri-hydroxyethyl ethers of triethanolamine is obtained by the action of an excess (at least 4 moles per mole of base) of ethylene oxide on aqueous ammonia.[65] These compounds possess the following formulas:



monohydroxyethyl ether



dihydroxyethyl ether

$$(HOCH_2CH_2OCH_2CH_2)_3N$$

trihydroxyethyl ether

Since from a theoretical standpoint such condensation reactions can be extended almost indefinitely, the number of higher condensation products would seem to be almost limitless.

In general, the homologues of ethylene oxide react less readily with ammonia. Krassuski and Duda[66] found that hexene-2 oxide reacts very slowly with ammonia at ordinary temperatures. After several hours' heating in a sealed tube at 100° C. the product was mainly the monohexanolamine,

$$CH_3CH(OH)CH(NH_2)CH_2CH_2CH_3$$

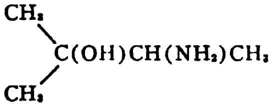
or

$$CH_3CH(NH_2)CH(OH)CH_2CH_2CH_3$$

with some secondary amine as a by-product. Under similar conditions tetramethylethylene oxide yielded the monoamine,

$$(CH_3)_2C(OH)C(NH_2)(CH_3)_2$$

Trimethylethylene oxide reacted very slowly with 33 per cent aqueous ammonia (not at all with anhydrous ammonia) at ordinary temperatures, but heating at 100° C. for some hours resulted in the formation principally of the monoamine

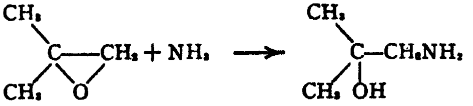


with only small amounts of the secondary product. In the same way, isobutylene oxide reacted with concentrated aqueous ammonia to give the aminotrimethylcarbinol,

---

[65] I. G. Farbenindustrie A.-G., British Patent 364,000, 1930; *Brit. Chem. Abs.* **B**, 1932, 495; French Patent 713,382, 1931; *Chem. Abs.*, 1932, **26**, 1733; French Patent 713,998, 1931; *Chem. Abs.*, 1932, **26**, 1619.

[66] *J. pr. Chem.*, 1908, (2) **77**, 84; *Chem. Abs.*, 1908, **2**, 2226; *J. Russ. Phys.-Chem. Soc.*, 1907, **36**, 1061; *Chem. Abs.*, 1908, **2**, 1124.



together with large amounts of the secondary compound and a small quantity of the tertiary amine.

Cyclohexene oxide reacts similarly with ammonia to yield 2-aminocyclohexanol,[67] and cyclopentene oxide and aqueous ammonia at 110° C. form trans-2-aminocyclopentanol.[68]

Primary and secondary amines can be condensed with olefin oxides, just as ammonia can, to yield the corresponding alkyl- and aryl-amino alcohols. The presence of water exerts a remarkable influence and is frequently absolutely essential. In some instances, as in the reaction between monomethylaniline and ethylene oxide to produce the amino alcohol having the formula

$$C_6H_5N(CH_3)CH_2CH_2OH$$

water does not appear to exert any influence on the yield.[69] A series of alkylamino alcohols has been prepared by condensing ethylene oxide with aliphatic amines.[70] Of the simple condensation products of olefin oxides with cyclic bases, cyclohexylethanolamine is prepared from cyclohexylamine and ethylene oxide.[71] The hydroxyalkylamines made from primary or secondary amines (containing at least one chain of more than 8 carbon atoms) and olefin oxides are said to be wetting agents.[72] Condensation products of hydroxyl-free amines or amides (such as octadecylamine or amides of oleic, stearic, naphthenic acids or p-toluenesulphonic acid) and polyethylene glycols (or a corresponding quantity of ethylene oxide or halohydrin) have been suggested as textile reagents.[72a]

Ethylene oxide does not react with pure dry diethylamine, but in the presence of water, or better of methyl or ethyl alcohol, a smooth and rapid absorption of the oxide takes place.[73] The initial product is β-diethylaminoethanol (Formula I, below), which can be prepared in good yields by passing the gaseous oxide into a solution of diethylamine (in water or alcohol) at 45° to 60° C. until about 0.5 mole of oxide is absorbed per mole of amine. As the proportion of ethylene oxide is increased, the amount of unreacted amine diminishes, but the products contain a number of substances boiling above β-diethylaminoethanol. From these higher boiling compounds may be separated the mono-β-diethylaminoethyl ether of ethylene glycol (Formula II) and the mono-β-diethylaminoethyl ether of diethylene glycol (Formula III). The two highest boiling fractions appeared to consist of the mono-β-diethylaminoethyl ether of triethylene glycol (Formula IV) and tetraethylene glycol (Formula V), respectively. These substances represent the progressive addition of ethylene oxide molecules to diethylamine and their formation may be indicated as follows:

---

$$\downarrow \text{(+ ethylene oxide)}$$

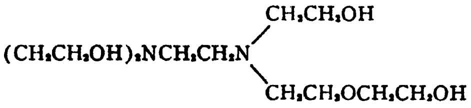
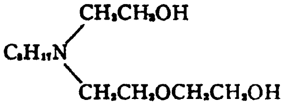
$$(C_2H_5)_2N(CH_2CH_2O)_4CH_2CH_2OH \qquad \text{(Formula V)}$$

Many other examples of this progressive addition of olefin oxide molecules to primary and secondary amines are known. Hydroxylated ethers of tertiary β-hydroxyalkylamines are made by condensing an amine (primary or secondary) with an excess (at least n + 1 moles of olefin oxide for n replaceable hydrogen atoms in the base) of olefin oxide in an aqueous medium.[74] Condensation of ethylene oxide and ethylenediamine in the molar proportions of 5 : 1 yields a material of the constitution,



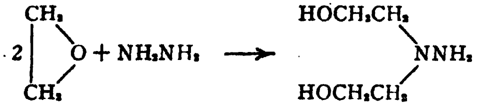
$$(CH_2CH_2OH)_2NCH_2CH_2N\begin{cases}CH_2CH_2OH\\CH_2CH_2OCH_2CH_2OH\end{cases}$$

The product of the reaction of 1 mole of octylamine with 3 moles of ethylene oxide has been assigned the formula[75]



$$C_8H_{17}N\begin{cases}CH_2CH_2OH\\CH_2CH_2OCH_2CH_2OH\end{cases}$$

Hydrazine and its derivatives can unite in a similar way with olefin oxides. Thus, hydrazine itself readily combines with the oxide to give bis-ethanol-hydrazine,[76]



Phenylhydrazine reacts with ethylene oxide to yield a more complex product.[77]

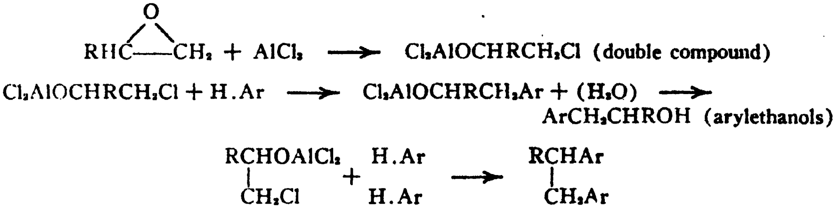
DIRECT ADDITION OF OLEFIN OXIDES TO HYDROCARBONS

The condensation of ethylene oxide with aromatic hydrocarbons, under the influence of aluminum chloride or other Friedel-Crafts condensing agent, was demonstrated by the work of Schaarschmidt, Hermann and Szemzö.[78] They obtained dibenzyl, together with a small amount of β-phenylethanol, by passing a mixture of ethylene oxide and hydrogen chloride into a mixture of benzene and aluminum chloride. This reaction has been re-examined by Smith and Natelson,[79] who also obtained dibenzyl and its homologues, together with phenylethanols as by-products. The formation of intermediate double compounds between the olefin oxide and anhydrous aluminum chloride probably constitutes the first phase of the reaction. These double compounds then react with the aromatic hydrocarbon in one of two ways as follows:



$$RHC\overset{O}{\text{——}}CH_2 + AlCl_3 \longrightarrow Cl_2AlOCHRCH_2Cl \text{ (double compound)}$$

$$Cl_2AlOCHRCH_2Cl + H.Ar \longrightarrow Cl_2AlOCHRCH_2Ar + (H_2O) \longrightarrow ArCH_2CHROH \text{ (arylethanols)}$$

$$\begin{array}{l} RCHOAlCl_2 \\ | \\ CH_2Cl \end{array} + \begin{array}{l} H.Ar \\ \\ H.Ar \end{array} \longrightarrow \begin{array}{l} RCHAr \\ | \\ CH_2Ar \end{array}$$

(R represents a hydrocarbon radical or hydrogen and Ar an aromatic nucleus). By the addition of 1 mole of ethylene oxide to a well-cooled mixture of 1 mole of anhydrous aluminum chloride and 6 moles of benzene followed by decomposition of the reaction mixture with water, Smith and Natelson isolated 65 per cent of dibenzyl and 5 per cent of β-phenylethanol.

This condensation has been extended to the preparation of numerous hydroxy derivatives of aliphatic, alicyclic, aromatic or heterocyclic compounds (not containing reactive amino, hydroxy or carboxyl groups). Reaction is effected at temperatures varying from —10° to 100° C., best under pressure, and in the presence of a condensing agent such as aluminum halides, boron trifluoride or anhydrous ferric chloride.[80] Inert organic diluents (carbon disulphide or tetrachloride) are used. Examples are the condensation of ethylene oxide with benzene to yield β-phenylethanol, with n-pentane to form n-heptanol, with naphthalene to give β-naphthylethanol, and with cyclohexane to produce β-cyclohexylethanol. When the oxide is condensed with kerosene a mixture of primary alcohols is obtained. Under similar conditions ethylene chloride and oxide form a mixture of ethylene chlorohydrin and 1,4-butylene chlorohydrin. With pyridine this oxide yields hydroxyethylpyridines.

REACTION WITH CYANIDES

When olefin oxides are heated for some time with anhydrous hydrogen cyanide, or with solutions or suspensions of cyanides, combination takes place with the formation of cyanohydrins[81]:

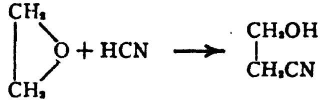
---

[78] *Ber.*, 1925, 58, 1914.

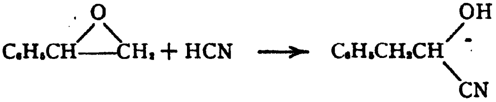
[79] *J.A.C.S.*, 1931, 53, 3476.

[80] I. G. Farbenindustrie A.-G., British Patent 354,992, 1930; *Brit. Chem. Abs.* B, 1932, 12; French Patent 716,604, 1931; *Chem. Abs.*, 1932, 26, 2198. See also Hitch and Dahlen, U. S. Patents 1,893,283 and 1,893,284, Jan. 3, 1933; both patents assigned to E. I. duPont de Nemours and Co., Inc.; *Chem. Abs.*, 1933, 27, 2298.

[81] Erlenmeyer, *Ann.*, 1878, 191, 269; Hörmann, *Ber.*, 1879, 12, 23.



The reaction occasionally takes an abnormal course as styrene, for example, yields the cyanohydrin of phenylacetaldehyde,[82] possibly because of isomerization:

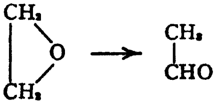


Alkylene cyanohydrins are prepared also by the reaction of olefin oxides with dispersions of the cyanides of alkali or alkaline earth metals in hydroxylic solvents (water, alcohols or mixtures of these).[83] The reaction temperature is maintained between 10° C. and 30° C. The cyanide may be regenerated continuously or intermittently by passing hydrogen cyanide into the solution or suspension of the hydroxide formed.

Isomerization of Olefin Oxides

Besides the above-mentioned purely additive reactions of the olefin oxides, there are also two important reactions of a very different type, namely, isomerization or intramolecular rearrangement, and polymerization. These oxides in the vapor state are isomerized to the corresponding aldehyde or ketone by heat or catalysts or, in the liquid phase, in the presence of hot dilute acids.

When passed through a glass tube at about 500° C., or in the presence of an alumina catalyst at 200° to 300° C., ethylene oxide is converted into acetaldehyde[84]:



The isomerization of ethylene oxide into acetaldehyde in the presence of various catalysts has also been studied by Krassuski,[85] Nef,[86] Peytral,[87] Kaschirsky,[88] and Fourneau and Tiffeneau,[89] and the kinetics of the thermal isomerization in the presence of pyrex glass was investigated by Heckert and Mack.[90]

The reaction is not confined to ethylene oxide as its immediate homologues undergo the reaction more readily. In the presence of alumina at 200° to 300° C., propylene oxide yields mainly propionaldehyde with smaller amounts of acetone; isobutylene oxide, isobutyraldehyde; and trimethylethylene oxide, methyl isopropyl ketone.[91] Dilute mineral acids are active in promoting this isomerization. For instance, dilute sulphuric or sulphurous acids convert methylstyrene oxide into the corresponding aldehyde[92]:

Isomerization of olefin oxides to aldehydes (or ketones) can be effected by passing them at 180° to 300° C. over a catalyst consisting of magnesium pyrophosphate, copper sulphate or cerous sulphate, with or without the addition of metallic oxides, hydroxides or carbonates, on a carrier.[93] Under these conditions propylene oxide yields propionaldehyde, allyl alcohol and acetone, and the oxides of butene-1 and butene-2, n- and iso-butyraldehydes, methyl ethyl ketone and butenols. Another group of catalysts comprises the halides or oxyhalides of the alkaline earth metals, including magnesium and beryllium.[94]

A mixture of propionaldehyde and allyl alcohol is obtained by conducting propylene oxide vapors, diluted with nitrogen, over activated aluminum at 200° to 400° C.[95]

The passage of 100 parts of ethylene oxide at 220° C. over silica gel impregnated with tungsten oxide at a velocity of 120 to 200 grams per hour per liter of catalyst gives, according to Kathol,[96] 95 to 98 parts of a condensate containing 75 per cent of acetaldehyde, and in addition various by-products such as paraldehyde, crotonaldehyde, dioxan and unsaturated hydrocarbons.

1,2-Oxides derived from cyclic olefins are said to be isomerized to the corresponding ketones by heating in the presence of catalysts such as magnesium sulphate, copper pyrophosphate or silica gel.[97] Thus, menthene-3 oxide yields menthone by heating with 5 per cent silica gel in a closed vessel at 250° C. for two hours. Under similar conditions cyclohexanone is made from cyclohexene oxide.

The isomerization of a number of α-oxides derived from aryl-substituted olefins, including phenyldialkylethylene oxides,[98] styrene oxide,[99] and phenylcyclohexene oxide,[100] has been investigated.

POLYMERIZATION OF OLEFIN OXIDES

Ethylene oxide, and olefin oxides as a class, provide excellent examples of the polymerization of cyclic compounds not involving double bond unsaturation. Treating ethylene oxide with various polymerizing agents such as strong bases (sodium hydroxide, trimethylamine or triethylphosphine) or certain inorganic halides (zinc chloride or tin tetrachloride) produces a profound and highly exothermic condensation.[101] The product is a semi-solid, readily soluble in water and in most organic solvents. It is separable by fractional crystallization into fractions having apparent molecular weights varying from 400 to nearly 5000. The fraction having the lowest molecular weight is a liquid, while the one having the highest is a solid melting at about 59° C. On heating, the polyethylene oxides yield a complex mixture of products containing some acetaldehyde and acrolein.

It is generally agreed that these polymerized oxides possess a long chain of $—(CH_2CH_2O)—$ residues linked alternately through carbon and oxygen atoms, but the exact configuration of the terminal groups is still uncertain. Roithner[102] assigned the following cyclic structure to the polymerized substances:

$$O—CH_2—CH_2—O—CH_2—CH_2— \ldots\ldots\ldots —O—CH_2—CH_2$$

On the other hand, it appears likely that, in some preparations at least, the terminal groups are hydroxyl groups (due to hydration) and the molecule is thus an open chain.[103]

Wax-like polymerides of olefin oxides are obtained by passing them in the vapor state over alkaline catalysts (sodium or potassium hydroxide) at temperatures from 40° to 200° C.[104] If acid catalysts, e.g., aluminum sulphate or sodium bisulphate, are employed, dioxan and its homologues are formed.

Various technical applications have been suggested for the viscous or solid polymerized olefin oxides. They may be used as ingredients of lacquer and coating compositions in conjunction with cellulose esters,[105] as dispersing agents,[106] as impregnating agents for waxes, resins, rubber, leather or paper,[107] and in the preparation of grounding or priming compositions useful as wood fillers.[108]

HYDROGENATION OF OLEFIN OXIDES

The reduction of olefin oxides, in aqueous solution, to the corresponding alcohols by sodium amalgam has long been known.[109] Alcohols are produced also by vapor-phase catalytic hydrogenation. Ethyl alcohol, for example, is obtained by the reduction of ethylene oxide by an excess of hydrogen at 80° C. under pressure in the presence of a catalyst of nickel on barium oxide. When ethylene oxide is in excess and higher temperatures (130° to 150° C.) are employed, glycol monoethyl ether is formed.[110]

Propylene oxide and hydrogen in the presence of a nickel catalyst at 170° C. yield n-propanol. Butylene oxide similarly gives butyl alcohol, and styrene oxide is converted to phenylethyl alcohol.[111] Propyl alcohol is made also by passing a mixture of propylene oxide and hydrogen (in the molal ratio of about 1:4) and about 10 per cent water vapor first over an aluminum catalyst (at 275° C.) and then over a reduced nickel catalyst (at 150° C.).[112]

USES OF ETHYLENE OXIDE

The most important uses of ethylene oxide at present are as a chemical raw material in the preparation of glycol ethers and ethanolamines, and as a fumigant and insecticide. Its application in industrial synthesis has already been mentioned. The use of ethylene oxide as an insecticide was investigated by Cotton and Roark,[113] who reported its vapor to be completely toxic to a number of different kinds of insect pests in stored products at ordinary temperatures in concentrations of 1 to 2 pounds per 1000 cubic feet of space. Ethylene oxide was found to have pronounced powers of penetration with no harmful effects on solid foodstuffs, clothing, furniture, or metals. The comparative toxicity of ethylene oxide and other fumigants was tested by Hoyt,[114] who found that 2 pounds of this compound per 1000 cubic feet of air space were required during a 24-hour exposure at 75° to 80° F. to give a 100 per cent destruction of all the insects used in the test.

Since ethylene oxide is a combustible gas and its extensive use as a fumigant introduces certain hazards of fire and explosion, various means of suppressing these dangers have been investigated. Cotton and Young[115] observed that by mixing carbon dioxide with ethylene oxide the toxicity was considerably increased and the fire hazard reduced or eliminated according to the relative amount of carbon dioxide employed. It was shown by Jones and Kennedy[116] that to render ethylene oxide-air mixtures non-inflammable under all conditions at normal temperatures and pressures at least 7.15 volumes of carbon dioxide per volume of ethylene oxide are required. Further work by Back, Cotton and Ellington[117] indicated the desirability of using at least 7 pounds of carbon dioxide with 1 pound of ethylene oxide. The application of ethylene oxide-carbon dioxide mixtures in fumigation has been discussed by Russ.[118]

In connection with the use of ethylene oxide for the destruction of pests in foodstuffs, Südenorff and Kröger[119] stated that concentrations up to 320 grams per cubic meter have no adverse effect on the quality or flavor of the foods if the space is thoroughly aerated afterwards. According to Thomas,[120] exposure (in enclosed rooms) of infected dried fruits to a concentration of ethylene oxide of 2 pounds per 1000 cubic feet for 4 hours at 20° C. was sufficient to destroy eggs, larvae and pupae.

The use of ethylene oxide mixed with carbon tetrachloride, or other diluents, solvents or irritants, in insecticides was proposed by Taube, Schepss and

Kükenthal.[121] Germicidal and insecticidal preparations containing mixtures of ethylene and propylene oxides, carbon disulphide, or vinyl chloride with inert gases (nitrogen or carbon dioxide) in sufficient quantity to render the mixture non-inflammable, were suggested by the T. Goldschmidt A.-G.[122] A bactericide (formaldehyde) can also be added.[123] Solidified mixtures of ethylene oxide and carbon dioxide are stated to be vermin-destroying compositions.[124]

Although it has been repeatedly stated that ethylene oxide is relatively non-toxic to man, experimental evidence seems to indicate that it possesses decidedly toxic properties and that certain precautions are necessary when fumigating with it. Koelsch and Leder[125] studied the toxic action of ethylene oxide on animals at concentrations of 1 : 50 to 1 : 10,000 in air and found that severe and sometimes fatal symptoms were induced. Particularly noticeable were the diminution in weight due to changes in metabolism, with narcosis, coma and paralysis of the limbs. The toxicity of ethylene oxide was noted also by Walker and Greeson.[126] In experiments on cats exposed to various concentrations of ethylene oxide vapors, Müller[127] observed an initial stimulation of the nasal mucosa resulting in watering of the eyes, sneezing, licking of the lips and leading to difficult respiration, vomiting, and finally to death. He concluded that the accidental exposure of man to concentrations of 32 grams of ethylene oxide per cubic meter need not be feared, but thorough ventilation of rooms, after fumigation, is essential.[128]

Ethylene oxide mixed with low-boiling liquids, such as methyl ethyl ether and propane, can be used for the de-waxing of petroleum distillates.[129] The oil is added to the solvent in the liquid phase under pressure and the mixture cooled to —23° C. by self-evaporation of some of the solvent. The precipitated wax is removed by filtration. The liquid oxide, mixed with some methyl alcohol, has been suggested as a fuel for certain types of portable cigarette lighters.[130] Nitroglycerol, glycol dinitrate, cellulose nitrate and other organic nitrates can be stabilized by treatment with ethylene oxide.[130a]

DETECTION OF ETHYLENE OXIDE

Deckert[131] suggested the following method for detecting ethylene oxide in air. Two hundred cubic centimeters of air are drawn through 5 cc. of a 22 per cent sodium chloride solution which contains either phenolphthalein or bromothymol blue as an indicator. The solution is then heated for 1 minute at 100° C. If there is no color change the concentration of the oxide in air was less than

[128] The destructive action of ethylene oxide on various plants and shrubs when injected into the soil at the roots has been noted by Harvey, *Science*, 1931, **73**, 100; *Chem. Abs.*, 1931, **25**, 4082; *Phytopath.*, 1931, **21**, 126; *Brit. Chem. Abs.* **B**, 1931, 1150.

[129] Vorhees, U. S. Patent 1,862,874, June 14, 1932; assigned to Standard Oil Co. of Ind.; *Chem. Abs.*, 1932, **26**, 4168.

[130] Fisher, U. S. Patent 1,895,032, June 24, 1933; *Chem. Abs.*, 1933, **27**, 2559.

[130a] Werntz, U. S. Patent 1,846,926, Feb. 23, 1932; assigned to E. I. duPont de Nemours & Co., Inc.; *Chem. Abs.*, 1932, **26**, 2468.

[131] *Z. angew. Chem.*, 1932, **45**, 559; *Chem. Abs.*, 1932, **26**, 5877.

0.5 mg. per liter (phenolphthalein) or less than 0.1 mg. (bromothymol blue), and the air is safe.

Another test consists in passing 50 cc. of air through 1 or 2 cc. of a 40 per cent potassium sulphocyanide solution to which is added 1 cc. of a phenolphthalein solution (1:1000). If a red color does not appear after warming the test tube (holding it in the hand) for 2 minutes, the air is free of ethylene oxide.[182]

A quantitative determination, suggested by Deckert,[183] is based on the reaction between ethylene oxide and hydrochloric acid:

$$C_2H_4O + HCl \longrightarrow CH_2ClCH_2OH$$

A measured volume of air is led through 0.1*N* hydrochloric acid, containing 22 per cent of sodium chloride. The solution is heated to 70° C. to convert all the oxide into ethylene chlorohydrin. The excess hydrochloric acid is titrated with 0.1*N* sodium hydroxide, using methyl-orange as an indicator. Each cc. of 0.1*N* hydrochloric acid reacting represents 4.4 mg. of ethylene oxide.

Lubatti[184] reported that Deckert's method accounts for about 90 per cent of the ethylene oxide present in the air. He recommends that more soluble chlorides, particularly magnesium chloride, be substituted for sodium chloride. Furthermore, the chloride solution should contain the equivalent of at least 30 grams of chlorine per 100 cc.

The estimation of ethylene oxide by oxidation to carbon dioxide and water with potassium dichromate and sulphuric acid was described by Müller.[185]

ETHANOLAMINES

As previously stated in this chapter, the combination of aqueous ammonia with ethylene oxide results in the formation of a mixture of three basic substances which may be separated by distillation. The proportions of the three products depend largely on the relative proportions of the reactants, an excess of ethylene oxide favoring the formation of triethanolamine.[186] The three bases, and particularly their mixtures, are assuming a position of importance in chemical industry.
